AUTHORS' PREFACE TO THE FIRST EDITION

A NOTICEABLE feature of preser
taken in virus infections, and
an up-to-date account of the
proved to be the cause of human disease.

Our primary objective has been to provide a useful reference volume for the medical laboratory worker whether engaged in research or academic teaching, or confronted with the diagnosis of suspected cases of virus infection. At the same
il value to
;arding the
diagnosis,

resent may prove of real help to those members of the medical profession entrusted with safeguarding the health of His Majesty's Forces serving in different parts of the world, where specific virus diseases are endemic.

The demand upon our space for the inclusion of clinical data has compelled us to omit from this volume a certain amount of technical matter mainly of academic interest, but we have given in the text numerous references in order that those interested in such subjects may be able to refer to original papers. Throughout the book, the abbreviations adopted for the titles of journals cited in the reference columns conform to the contracted format recommended in the *World List of Scientific Periodicals*,[1] and we trust that the extensive bibliography will be of assistance to workers situated at a distance from libraries.

In this monograph we have not attempted strictly to classify virus infections, but we have grouped the various diseases according to the system mainly involved, in the following arbitrary order: skin diseases, infective fevers, tropical diseases, respiratory diseases, eye diseases, and diseases of the nervous system.

As a general rule, it will be found that the actual length of text devoted to any one disease depends more on the amount of relevant literature published than on the precise intrinsic importance of the particular subject. Where a certain virus is one which predominantly infects animals, and man but occasionally (e.g., foot-and-mouth disease and pseudorabies), its characteristics are only briefly described.

Viruses peculiar to animals or plants are not discussed, and likewise we have not dealt with the Rickettsiae, since our purview has been expressly limited to an account of only those diseases of man in which the causal agent has been definitely shown to come within the virus category, as at present generally accepted.

It is with considerable pleasure that we acknowledge the help and co-operation so kindly afforded us by many colleagues in Scotland and elsewhere.

Thus it was originally at the instigation of Professor Mackie, the head of our department, that the preparation of this book was undertaken, and we desire to express our warmest appreciation of his many welcome suggestions, constructive criticism, and valued counsel regarding the selection of subject matter, also for the Introduction which he has himself contributed.

To our friend Professor W. J. Tulloch of Dundee we owe our thanks for his many valuable suggestions in connection with the sections dealing with filtration
diseases of
fforded us
smallpox.

[1] Oxford University Press, 2nd edition, 1934

Similarly, Dr. Mervyn Gordon and Lt.-Col. W. D. H. Stevenson of London have extended to us the benefit of their wide experience of vaccination, smallpox, and related matters.

Next we should like to record the willing assistance received from the following members of the Edinburgh Medical School regarding certain subjects in which they are personally interested: Dr. A. E. Cameron (entomological aspects of yellow, sandfly, and dengue fevers); Dr. A. C. P. Campbell (poliomyelitis), Dr. S. W. Challinor (*the preparation of collodion membranes*), Lt.-Col. E. D. W. Greig (lymphogranuloma inguinale, Rift Valley, dengue, yellow, and sandfly fevers), Lt.-Col. W. F. Harvey (inclusions, trachoma), Lt.-Col. J. du P. Langrishe (certain sections on epidemiology); Lt.-Col. W. Glen Liston (yellow fever), Lt.-Col. A. G. McKendrick (rabies, pseudorabies), Dr. W. G. Millar (the microscope), and Dr. A. C. Stephen, Royal Scottish Museum (section on monkeys in yellow fever chapter).

We are very grateful to the following, who have kindly supplied certain photographs to illustrate the text. Col. L. T. Poole of the Royal Army Medical College, London (Negri bodies), Dr. V. Grysez of Lille (preparation of rabies vaccine), Professor E. G. Nauck of Hamburg (inclusions of lymphogranuloma), and Lt.-Col. W. D. H. Stevenson of London (vaccinial infection of the chorio-allantois). Illustrations reproduced from different sources have been individually acknowledged in the text and the remainder have been executed by ourselves, from our own preparations.

We cannot adequately express our appreciation to our colleagues Mr. James A. Ross and Dr. A. T. Wallace who have read the major part of the typescript, and Dr. R. K. Oag who has read all the proofs.

The heaviest burden of preparing this work for press has fallen on our secretary, Miss Frances L. Henderson, M.A., and we are particularly grateful to her *for the skill, untiring care, and painstaking attention which she has devoted to the* task entailed.

The writing of this book has entailed very extensive reference to libraries, and it gives us the greatest pleasure to take this opportunity of acknowledging the invaluable assistance so cheerfully given to us by the following librarians: Miss Charlton and Miss McIntosh of Edinburgh University, Mr. Graham and Miss Russell of the Royal College of Physicians, Edinburgh, Mr. Shields of the British Medical Association, London, *and the staffs of many other libraries throughout* Great Britain and the Continent, without whose patient co-operation the work could not have been accomplished.

In conclusion, we should like to remind the reader that the subject-matter of this book has been compiled, and the proofs corrected, largely during the troubled times between the months of September 1938 and December 1939, and although we have made every effort to avoid incorporating errors in the text, some doubtless will remain, and we therefore beg the indulgence of our readers for those which have escaped detection.

March, 1940

AUTHORS' PREFACE TO THE SECOND EDITION

The purpose of this book is to provide a volume of reference for both the laboratory worker and clinician interested in the field of human and animal virus

thalmology, respiratory diseases, and veterinary medicine. Likewise it should prove helpful to postgraduates preparing for examinations in these and related subjects.

We have adhered to our original plan of describing only those human diseases of virus origin in which the causal agent has been definitely established. Rickettsial infections of man, virus diseases of animals not known to be transmissible to man, plants, and insects, together with viruses responsible for tumor formation, have not been included.

Nearly ten years have passed since the first edition appeared, and in this time so many advances have taken place in the fundamental and applied aspects of virus research that a thorough revision of the text has become necessary. Thus the following chapters have been rewritten and expanded: The Electron Microscope, Use of the Fertile Egg for Virus Cultivation, Mumps; Yellow Fever, Influenza, Psittacosis, Epidemiology, Diagnosis, and Prevention of Smallpox, Antirabies Treatment; Poliomyelitis; St. Louis, Japanese, and North American Equine Encephalomyelitis. Among virus diseases described in this volume for the first time are, German measles, West Nile disease and related conditions, Colorado tick fever, Newcastle disease, epidemic keratoconjunctivitis, pneumonitis and atypical pneumonia, Venezuelan equine encephalomyelitis, Russian spring-summer encephalitis, infective hepatitis and serum jaundice Altogether some twenty new virus infections have been added, and reference is made to some others of lesser concern.

Today it is probable that virus diseases as a group occupy a more important position in human and veterinary medicine than do those of bacterial origin This fact was demonstrated during the recent war when infective hepatitis, serum jaundice, jaundice associated with yellow fever vaccination, pneumonitis, influenzal diseases, epidemic keratoconjunctivitis, dengue and sandfly fevers, poliomyelitis, and smallpox accounted for much disability over wide areas of the world

Virus diseases now occupy such a major position in the ecology of man and animals that detailed instruction to medical and veterinary undergraduates and postgraduates has become essential, and we hope that this publication will satisfy the needs of teachers called upon to impart such education.

We have acknowledgments to make to many of our friends, and colleagues in Toronto, who have willingly advised us in subjects in which they possess special knowledge Dr Frank Airey (diseases of the skin), Professor E. F Burton (electron microscopy), Mr F W Boswell (electron microscopy), Dr. John Crawley (equine encephalomyelitis and statistical methods), Dr W. E. Coutts (lymphogranuloma), Dr A. F Graham (physical chemistry), and Dr Laurella McClelland (influenza) Drs Crawley, Graham, and McClelland have very kindly assisted with proofreading

In this edition we have made reference to the main contribution to virus literature published up to the end of 1947, and have included some work published in the early months of 1948. For

thanks to many librarians in Lo

Mr Barnard and his assistant

Medicine, the Staff of the Bur

Librarian and his assistants at the British Medical Association Headquarters, Lon-

don; Miss Briggs, Librarian at the School of Hygiene, University of Toronto; Miss Jones and Mr. Wade of the Royal Society of Medicine, London. In conclusion, we acknowledge the generous financial aid of the Sir Halley Stewart Trust, London, which has facilitated the task of revision

CHAPTER I

THE MICROSCOPICAL EXAMINATION OF ELEMENTARY BODIES

THE USE OF THE ORDINARY MICROSCOPE FOR THE DEMONSTRATION OF ELEMENTARY BODIES

THE detection of elementary bodies has become a matter of considerable importance in the recognition of certain virus diseases, and in recent years these bodies have been demonstrated in, for example, vaccinia, variola, ectromelia, herpes, varicella, psittacosis, fowl-pox, canary-pox, infectious myxomatosis, and fibromatosis of rabbits. The value of the ordinary microscope for this purpose has been somewhat underrated.

The limit of visibility is stated by Coles (1929) to be 0·074 μ with ordinary white light and 0·0673 μ with green light. The macula of the retina is most sensitive to green light and, owing to the additional contrast which is imparted, a smaller object becomes more easily visible with green than with white light. It must be borne in mind that the employment of mordants for staining elementary bodies increases their size, so that although vaccinia virus may actually be 0·15 μ in diameter by ultrafiltration measurements, after staining it may appear to be 0·3 μ. With improvements in technique it is possible that viruses even smaller than 0·067 μ may be seen as stained particles. There are indications that further developments are likely to occur along these lines, and Merling-Eisenberg (1938), by taking advantage of the fact that the limit of visibility is greater in the dark field, has succeeded in photographing the particles of a *B. coli* bacteriophage which only measured 0·025 μ in diameter. A particle of such size lies on the borderline of visibility, and great skill and care are required to differentiate between virus particles and artefacts. The limit of visibility mentioned above must not be confused with the limit of resolution. The latter is generally stated to be 0·25 μ with direct light; this figure represents the smallest space that could be appreciated by the eye if two objects were placed near to each other. For example, if two parallel lines were gradually brought closer together, as soon as they were less than 0·25 μ apart it would be impossible to discern the gap existing between them and this distance would represent the limit of resolution. Thus, the two images would seem to have fused together and appear as a single straight line, according to Johnson (1928), an objective possessing a numerical aperture of 1.4 is able to resolve a space of 0·2 μ or separate 140,000 lines per inch.

When employing oblique illumination, the limit of resolution or separation is smaller still, and two refractile dots, viewed in a dark field, can be separated if they are situated less than 0·2 μ apart, and by means of darkfield illumination phage particles of the order of 25 mμ in size have been photographed by Merling-Eisenberg (1938).

While the limit of resolution with a lens of 1·4 N.A. is about 0·25 μ, the limit of visibility of this glass when used at full aperture is 0·074 μ for a deeply stained particle seen with ordinary white light, and 0·0673 μ for one viewed in green light (Coles, 1929).

this point more clear, for it will be observed that, although a particle of 0.2 μ in diameter can still be distinctly seen with the naked eye, it becomes more difficult to separate two lines placed 0.2 μ apart. That a gap really exists between these two lines there need be no doubt, for the reader has only to place a magnifying reading glass over the diagram when the two lines will become readily visible. Finally, with the help of the magnifying glass it may also be possible to detect the smallest circle of the series, which measures 0 1 μ in diameter, while two lines situated the same distance apart appear as a single image.

FIG ... the view seen under dark ground illumination

By means of these arguments and the assistance of the illustration we have provided, the reader may be able to convince himself that the limit of visibility is smaller than that of resolution

We stated that when employing darkground illumination both the limits of visibility and of resolution were enhanced This can be proved by a study of Fig 3 which consists of a negative prepared from Fig 2, showing the series of circles and parallel lines precisely as they would appear if seen as brightly illuminated objects against a dark background From a comparison of Figs. 2 and 3 it will be observed that the circles and spaces between the parallel lines are more easily visible in Fig 3 than in Fig 2 This is so because a stained particle viewed by direct light is always less easy to see than a brightly illuminated object of the same size placed against a dark background In other words, the contrast between the object and its background is greater in Fig 3 than in Fig 2, which results in increased visibility and particularly resolution when using darkground illumination To some extent, therefore, the limit of resolution can be increased by using a more powerful source of light and increasing the amount of contrast between the object and its surroundings A good example of a practical illustration showing this point is that of the fixed stars seen on a clear night Although these can be seen with the naked eye, they are in reality far below the limit of resolution of even the most powerful telescope, and their apparent magnitude, therefore, depends solely on their brightness against the black sky, thus the brighter the star, the larger it appears to be, irrespective of its real size

Optical equipment The choice of suitable equipment[1] is as important as the correct use of it, and strict attention should be paid to the maker's instructions

[1] The following apparatus has been found useful (van Rooyen, 1937) Patna microscope (Watson) fitted ...

(2) The most suitable substage condensers ... parachromatic dry condenser of N.A. 1 or, ... N A 1 3 or 1 7 With the latter, however, ... ess (see Bridges, 1936, for details regarding an oil-retaining level for oil immersion substage condensers)

The resolving power of a lens has been theoretically explained by Martin and Johnson (1931). Owing to the wave nature of light, an objective is unable to reproduce a sharply defined outline of a minute brightly illuminated object; instead of which it produces an image that consists of a central bright spot surrounded by a series of concentric diffraction rings. This phenomenon has been called the Airy (1834) disk, the radius of which (b') is deduced according to the formula $b' = \frac{0.61\lambda}{\sin U'}$, when λ = the wave length of light employed and U' = the angle between the marginal rays of the lens and its optical axis Hence, if two point objects be brought closer toward each other, it can be proved by means of an intensity curve drawing that the two images will be separated by a dark zone only at such a point when their centers are situated at a distance which is at least approximately equal to the radius of the Airy disk (see Martin, 1925–6).

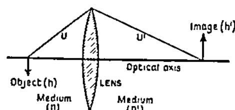

FIG 1. Diagram to explain formation of Airy disk.

By application of the sine relation to an optical system it can be shown from Fig. 1 that $nb \sin U = n'b' \sin U'$, where n and n' represents the refractive indices of the media lying on the object and image sides of the lens and U and U' the angles subtended by the marginal ray and the optical axis. In order to find the smallest distance between two objects conditional with resolution, b' must be substituted by the value of the radius of the Airy disk which is $\frac{0.61\lambda}{\sin U'}$, and accordingly

$$nb \sin U = n' \times \frac{0.61\lambda}{\sin U'} \times \sin U'.$$

But since the refractive index of the medium in which the image is formed is air and this is equal to unity, $b = \frac{0.61\lambda}{n \sin U'}$. But $n \sin U$ is equal to the numerical aperture (N.A.) of the lens (see Mackie and McCartney, 1948, for explanation), therefore $b = \frac{0.61\lambda}{\text{N.A.}}$. It can accordingly be stated that the resolving power of an objective is directly proportional to the wave length of light employed and varies inversely with the numerical aperture of the lens. In the following pages, with the help of a diagram, we shall describe a simple method by which the limit of visibility can be proved to be smaller than the limit of resolution.

The Limits of Visibility and Resolution Diagrammatically Explained

We have just mentioned that when using direct light the limit of visibility is smaller than the limit of resolution. In other words, it is easier for the human eye to perceive a deeply stained particle than to discern a space of the same size lying between two parallel lines. This fact can be demonstrated graphically by means of a scale drawing Let us presume that Fig. 2 represents a microscopic field viewed under ×1,000 magnification, showing a series of circular black dots, the largest of which measures ... se is a pair of parall ... ircle opposite to it ... 1 μ and the last and narrowest is 0.1 μ

A glance at the range of black spots, which may be assumed to represent deeply stained particles in a microscopic field, will immediately show that, whereas a minute black circle of 0.4 μ is readily visible, it is perhaps not so easy to see a gap of 0.4 μ between the corresponding parallel lines The next pair of objects makes

this point more clear, for it will be observed that, although a particle of 0.2 μ in diameter can still be distinctly seen with the naked eye, it becomes more difficult to separate two lines placed 0.2 μ apart. That a gap really exists between these two lines there need be no doubt, for the reader has only to place a magnifying reading glass over the diagram when the two lines will become readily visible. Finally, with the help of the magnifying glass it may also be possible to detect the smallest circle of the series, which measures 0.1 μ in diameter, while two lines situated the same distance apart appear as a single image.

Fig. 2

Fig. 3.

Fig 2. Diagram illustrating limits of visibility and resolution. The minified illustration was prepared from an accurate scale drawing made on graph paper in which the largest circle measured 1 cm. and the smallest 1 mm. The diagram was then reduced ten times so that the largest circle became 1 mm. and the smallest 0.1 mm. The drawing has been placed in a circular mask to convey the impression as seen in a ×1,000 microscopical field in which the largest circle was 1 μ in diameter. The distance between each set of parallel lines corresponds to the size of the adjacent circles.

Fig 3 is a negative print of Fig. 2 and represents the view seen under dark ground illumination.

By means of these arguments and the assistance of the illustration we have provided, the reader may be able to convince himself that the limit of visibility is smaller than that of resolution.

We stated that when employing darkground illumination both the limits of visibility and of resolution were enhanced. This can be proved by a study of Fig. 3 which consists of a negative prepared from Fig 2, showing the series of circles and parallel lines precisely as they would appear if seen as brightly illuminated objects against a dark background. From a comparison of Figs. 2 and 3 it will be observed that the circles and spaces between the parallel lines are more easily visible in Fig 3 than in Fig. 2. This is so because a stained particle viewed by direct light is always less easy to see than a brightly illuminated object of the same size placed against a dark background. In other words, the contrast between the object and its background is greater in Fig. 3 than in Fig. 2, which results in increased visibility and particularly resolution when using darkground illumination. [illegible]

naked eye, they are in reality far below the limit of resolution of even the most powerful telescope, and their apparent magnitude, therefore, depends solely on their brightness against the black sky, thus the brighter the star, the larger it appears to be, irrespective of its real size.

Optical equipment The choice of suitable equipment[1] is as important as the correct use of it, and strict attention should be paid to the maker's instructions

[1] The following apparatus has been found useful (van Rooyen, 1937) Patna microscope (Watson) fitted with rackwork draw-tube, universal mechanical stage *and centering* substage mechanism, compensating eyepieces ×10, ×15, and ×20, apochromatic objectives, 2 mm (1/12 in oil immersion) of N A *1·4 (Leitz)* or 2 mm. holoscopic objective of N A 1·30 (Watson), 8 mm dry apochromatic objective of N A 0·65 (Zeiss), and 6L dry achromatic objective of N.A. 0·65 (Leitz) *The most* suitable substage condensers have been found to be either the (Watson) parachromatic dry condenser of N A 1 or, better the holoscopic oil immersion model of N A *1·3* or *1·7* With the latter, however, the slides must not exceed 1·3 mm in thickness (see Bridges, 1936, for details regarding an oil-retaining level for oil immersion substage condensers).

FIG 4 Photomicrograph taken with the ordinary microscope, showing the elementary bodies of vaccinia viewed in the darkground field. The picture was taken with a Leitz 6L dry high-power objective and ×14 ocular, the total magnification is ×630.

regarding the optimum conditions under which each lens is designed to function. The source of illumination that we have found most suitable for this class of work has been that provided by a short filament high-intensity electric lamp bulb, and a lamp containing a 12-volt 4-amp. bulb should be fitted with a condenser and an

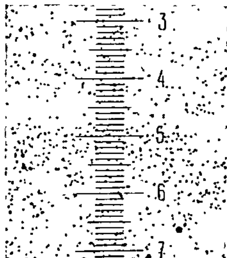

FIG 5. Photomicrograph made from a film preparation of vaccinia virus cultivated in the chorio-allantoic membrane of the chick embryo, showing Paschen or elementary bodies

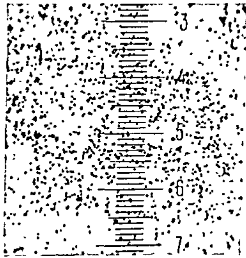

FIG 6 Similar picture made from a film of conjunctival secretion obtained from a rabbit infected with myxoma virus, showing elementary bodies

(Reproduced from *Glas med J*, 1938, *129*, 1)

iris diaphragm for darkfield and critical brightfield illumination, as well as a ground-glass screen for direct observations.

Before examining a preparation for elementary bodies it is necessary to insure that the incandescent filament, substage condenser, objective, and eyepiece are accurately centered and in perfect alignment, for with particles of less than 0.3 μ critical illumination is imperative. Stained films should be made on slides of 1.1 mm. thickness, and should be mounted preferably in cedar-wood oil. It is also advantageous to use only preparations which have been previously compressed between two heavy weights for 24 hours, in order to insure that the coverslip and slide are brought as close as possible to each other. The preparation should be viewed first by direct light with the low-power dry objective to ascertain the types of cells present, and then a 2 mm. oil immersion objective with ×10 and ×15 oculars can be used to search for elementary bodies Fields showing only scanty elementary bodies should be disregarded and, if possible, clumps of them should be sought. Individual bodies or pairs should be moved into the center of the field and carefully scrutinized, first with the ×10 and then the ×15 ocular, the fine adjustment should be continuously used and the height of the substage condenser varied in order to focus accurately the light upon individual particles The substage condenser diaphragm aperture may also be slightly closed in order to give greater depth of focus, and a green filter can be used with added benefit, so as to impart greater contrast to the particle The length of the microscope drawtube should also be adjusted to suit the coverslip and slide thickness (see Martin and Johnson, 1931). Each stained film made from pathological material intended to be examined for elementary bodies should be accompanied, if possible, by two control specimens, one from a similar source of normal tissue, and the other from a specimen which is known to contain elementary bodies, for, unless such controls are included in each series, erroneous conclusions are likely to ensue All three slides should be stained together and examined consecutively. The staining reactions and morphology of any virus bodies having been noted, the same field should next be examined by darkground illumination This can be done by revolving the nosepiece bearing the 2 mm objective away from the slide (which should be firmly fixed to the microscope stage with spring clips), wiping the oil from the surface of the coverslip with a piece of muslin, and then moving either the 6L[1] or 8 mm[1] lens into position The objective should next be focused upon the slide, the ground-glass lamp screen removed, both iris diaphragms fully opened, and a patch stop or a Travis's expanding stop inserted into position in the condenser substage ring Darkground illumination is now obtainable and it should be possible to determine whether or not the stained elementary bodies previously seen in the field are also refractile to obliquely transmitted light (Fig 4) By reversing the steps detailed

FIG 7 Film showing a mixed culture of staphylococci and *B coli* for comparison with elementary bodies shown in Figs. 5 and 6

All three have been stained by the same method, i e Paschen's stain for elementary bodies Each division on the micrometer scale –1.2μ. The magnification –×1,222

(Reproduced from *Glas med. J*, 1938, *129*, 1.)

above, it should be possible to restore the direct illumination for the same field This method enables an observer to study a stained preparation first by direct light and next by darkground illumination, without moving the field or having to do any more than insert a Travis's patch stop into the substage condenser.

Figures 5 and 6 show the appearance of elementary bodies when stained and photographed with the light microscope. Figure 7 may be used for comparison

FLUORESCENCE MICROSCOPY

Hagemann (1937) has demonstrated the value of the fluorescence microscope as an aid to the study of virus bodies, which can be made to fluoresce either by directly irradiating them with ultraviolet light or by first treating them with a fluorescent dye such as yellow 2 G.S, a diazo-amino compound of primulin. When examined under the fluorescence microscope the dyed elementary bodies appear as white or bluish-white particles lying upon a darkly colored background. The method has also been used to examine elementary bodies within living cells.

Sources of ultraviolet light.

Barnard and Welch (1936) state that the best fluorescent effects are exhibited by organisms viewed under darkground illumination and consequently an intense source of ultraviolet light must be used in order to get the best results The carbon or metallic arc may be used, [illegible]
too low an ultraviolet light ou [illegible]

The mercury vapor lamp i [illegible]
is high, its intrinsic brilliancy [illegible]
area, and consequently it is unsuitable for microscopy. Both of the above-described varieties of illuminant are also unsatisfactory because they necessitate the use of a filter in order to absorb the visible rays and there is consequently much loss of brilliancy in the darkground field

[illegible] arge—this is produced between magnesium
[illegible] Wel [illegible]
[illegible] it of [illegible]
[illegible] ioresc [illegible]
ultraviolet light photo-micrography.

Optical equipment The following components are required an ultraviolet light lamp, a quartz or crown glass collecting lens, and a suitable filter. The microscope should be fitted with a quartz darkground substage illuminating condenser and the ordinary glass reflecting mirror replaced by a polished metal one. Fluorescence may be observed visually through ordinary apochromatic objectives with compensating eyepieces, but if photographs with ultraviolet light be required, then quartz objectives must be employed

Material for examination should be spread on quartz slides, treated with primulin (*vide infra*), mounted in Ringer's solution, physiological saline, or distilled water, and covered with a type of cover-glass that is opaque to ultraviolet rays.

Himmelweit (1937) has used vertical illumination[1] for his experiments on fluorescence microscopy and has studied the multiplication of vaccinia virus in the chorio-allantoic membrane of the developing chicken embryo

Procedure.

1 Material containing the virus is spread on a quartz glass slide.
2. It may be fixed, if required, with 96 per cent. alcohol or 1 to 4 per cent formalin for 5 to 10 minutes before staining.
3 Treat with a 0.1 per cent solution of primulin containing 0 2 per cent phenol in distilled water for 15 seconds.

[1] Leitz Ultropak outfit

4 Wash with distilled water, dry, and examine, suitably mounted, under the fluorescence microscope.

When using living tissues phenol should be omitted from the "fluoro-chrome" solution. Primulin is the most effective dye for this class of work and it dissolves in water to produce a bluish fluorescence, which is transferred to organisms impregnated with it.

Hagemann (1937) states that the use of the dye makes it possible to detect certain morphological details that would otherwise be unrecognizable in canarypox, vaccinia, and ectromelia viruses. He also recommends the principle for the morphological study of bacteria and trypanosomes. For other work on fluorescence microscopy see Kufferath (1935), Sutro (1936), and Haitinger (1938).

PHASE MICROSCOPY

Since Zernicke (1935) described this method, further research by Bennett *et al.* (1946) has revealed its possibilities for the examination of unstained biological material The value of the phase contrast technique in the study of virus elementary bodies is yet unexplored.

CHAPTER II

THE MAGNETIC ELECTRON MICROSCOPE

We have already explained on page 2 that the shorter the wave length of light used, the *greater the resultant resolution and useful magnification obtained* More- [illegible] (Hawley, 1945) that to be visible or distin- [illegible] one half of the wave length of light used [illegible] is able to resolve 1/250 inch or 100 μ or 1,000,000 Angstrom Units.[1] Ordinary white light of the visible spectrum has a wave length of *400 to 800 mμ (equivalent to 4,000–8,000 Angstrom Units), a useful* magnification of ×1,200 is attainable with the best optical equipment, the smallest particles discernible in a stained slide are in the region of 67 mμ or 670 A.U.

Ultraviolet light has a wave length of 360 mμ (equivalent to under 3,600 A.U.) and since it is about half that of ordinary light, resolution becomes doubled, a magnification of ×3,200 can be obtained *with increased definition and the morphology* of structures smaller than 67 mμ can be seen. The disadvantage of the instrument is that although a relatively small increase in resolution is gained, the instrument and quartz lenses are hard to fashion, stained preparations cannot be viewed, and the photographic plate is substituted for direct visual observation

The wave lengths of electron rays employed in the electron microscope are extremely short, and measure approximately 0·05 A U. In consequence still higher resolution and useful magnification can be attained up to at least ×100,000 if 10 A.U. are resolved, with excellent definition and great depth of focus Thus, particles of matter possessing very small dimensions, in the region of 10 A U., are brought within the theoretical limit of resolution The limit of resolution of the 1944 Toronto University model is about 50 A U, owing to inhomogeneity of the iron pole pieces By using a special technique with the R C A. model E.M U, resolution of 10 A.U. may be attained with a specimen such as gold particles, this resolution may be limited, however, by lack of sufficient density in biological particles. Readers interested in the theoretical limits of electronic micoscopy should read the publication of Zworykin, Morton, Ramberg, Hillier and Vance (1945).

PHYSICAL PRINCIPLES

The instrument has been developed from the work of Marton (1934, *1934a, 1935, 1936, 1937), Martin, Whelpton, and Parnum (1937)*, von Borries, Ruska, and Ruska (1938), and Burton, Hillier, and Prebus (1939, 1940) The latter effected considerable improvement so that today it is possible to obtain photographs of bacteria and viruses magnified ×100,000 times with good definition The instrument utilizes the physical principle that free electrons and beams of electrons can be deflected by an electromagnetic field To adopt this method for optical purposes, the magnetic fields have been applied in such a way that they act on the electron beam in the same manner as optical lenses do on beams of light Such a field or "magnetic lens" can be produced by a current-carrying coil, as shown in Fig 8 The coil is enclosed in an iron casing which leaves a narrow annular slit at 90° to the axial point where the maximum concentration of field is required. When the current flows through the coil, the free ends of the iron casing are *transformed* into magnetic poles, and between them a magnetic field develops possessing the properties of a convex lens, and the path of a ray of electrons through such a lens is illustrated in Fig. 8 It is, however, complicated by the fact that the electrons,

[1] *Angstrom* Unit = 0·1 mμ = 10^{-} mm = 10^{-8} cm or 1/250,000,000 inch

while passing through the coil, are not only deflected from their original direction in the plane of the drawing, but also spirally around the axis of the coil.

In every single point of the curve, it is only the magnetic component perpendicular to the momentary direction of the ray which acts on it, and produces a

originates which, from
he surface of a spindle.
but can be varied by
the magnetic field and,

consequently, the focal length of the lens. As the focal length varies, the electron-optical image not only becomes more or less sharp, but, over and above that, turns

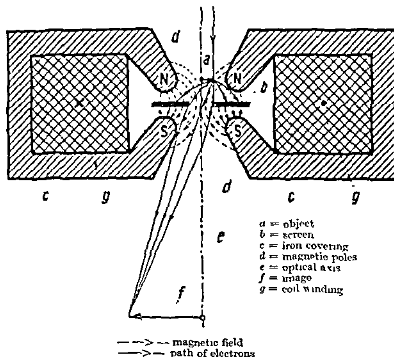

FIG 8 Diagram showing the path of electron rays through an electromagnetic lens, illustrating the principle of the electron microscope constructed by von Borries *et al* (1938).

(Reproduced from *Klin Wschr*, 1938, *17*, 921)

on itself, i e, around the optical axis, in accordance with the spiral ray deflection described Loss of efficiency arising from the latter has been overcome in the latest Radio Corporation of America E.M.U. type model, and resolution in the region of 10 A U has been attained

Since electron beams can exist only in a vacuum, any object which is to be inspected by an electron-optical system must itself be placed within the vacuum, and since electron beams are not directly visible to the eye, the image formed must be made visible either by a fluorescent screen or recorded on a photographic plate

Mechanism of Image Formation

Burton and Kohl (1946) have explained that the principle governing image formation in the electron microscope differs from that of the ordinary light instru-

CHAPTER II

THE MAGNETIC ELECTRON MICROSCOPE

We have already explained on page 2 that the shorter the wave length of light used, the greater the resultant resolution and useful magnification obtained. Moreover, it can be shown diagrammatically (Hawley, 1945) that to be visible or distinguishable an object must be larger than one half of the wave length of light used to illuminate it. The unaided human eye is able to resolve 1/250 inch or 100 μ or 1,000,000 Angstrom Units.[1] Ordinary white light of the visible spectrum has a wave length of 400 to 800 mμ (equivalent to 4,000–8,000 Angstrom Units); a useful magnification of ×1,200 is attainable with the best optical equipment, the smallest particles discernible in a stained slide are in the region of 67 mμ or 670 A.U.

Ultraviolet light has a wave length of 360 mμ (equivalent to under 3,600 A.U.) and since it is about half that of ordinary light, resolution becomes doubled, a magnification of ×3,200 can be obtained with increased definition and the morphology of structures smaller than 67 mμ can be seen. The disadvantage of the instrument is that although a relatively small increase in resolution is gained, the instrument and quartz lenses are hard to fashion, stained preparations cannot be viewed, and the photographic plate is substituted for direct visual observation.

The wave lengths of electron rays employed in the electron microscope are extremely short, and measure approximately 0·05 A.U. In consequence still higher resolution and useful magnification can be attained up to at least ×100,000 if 10 A.U. are resolved, with excellent definition and great depth of focus. Thus, particles of matter possessing very small dimensions, in the region of 10 A.U., are brought within the theoretical limit of resolution. The limit of resolution of the 1944 Toronto University model is about 50 A.U., owing to inhomogeneity of the iron pole pieces. By using a special technique with the R.C.A. model E.M.U., resolution of 10 A.U. may be attained with a specimen such as gold particles, this resolution may be limited, however, by lack of sufficient density in biological particles. Readers interested in the theoretical limits of electronic micoscopy should read the publication of Zworykin, Morton, Ramberg, Hillier and Vance (1945).

PHYSICAL PRINCIPLES

The instrument has been developed from the work of Marton (1934, 1934 *a*, 1935, 1936, 1937), Martin, Whelpton, and Parnum (1937), von Borries, Ruska, and Ruska (1938), and Burton, Hillier, and Prevbus (1939, 1940). The latter effected considerable improvement so that today it is possible to obtain photographs of bacteria and viruses magnified ×100,000 times with good definition. The instrument utilizes the physical principle that free electrons and beams of electrons can be deflected by an electromagnetic field. To adopt this method for optical purposes, the magnetic fields have been applied in such a way that they act on the electron beam in the same manner as optical lenses do on beams of light. Such a field or "magnetic lens" can be produced by a current-carrying coil, as shown in Fig. 8. The coil is enclosed in an iron casing which leaves a narrow annular slit at 90° to the axial point where the maximum concentration of field is required. When the current flows through the coil, the free ends of the iron casing are transformed into magnetic poles, and between them a magnetic field develops possessing the properties of a convex lens, and the path of a ray of electrons through such a lens is illustrated in Fig. 8. It is, however, complicated by the fact that the electrons,

[1] Angstrom Unit = 0·1 mμ = 10^{-7} mm = 10^{-8} cm or 1/250,000,000 inch

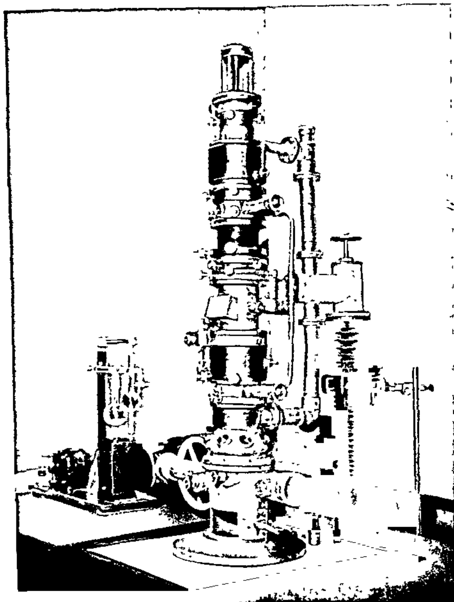

FIG 10 The electron microscope, University of Toronto (1944) type

Industries, Ltd., of Holland, and Metropolitan Vickers, Ltd, of England (Zworykin and Hillier, 1943) Developments continued at the Department of Physics, Toronto University, and Drs Newman and Watson evolved a much improved machine, component parts of which are illustrated in Figs 9–10. Details are as follows Within the electron gun (G) is a tungsten filament, (S) the cathode shield is at the same potential as the filament and produces an electrostatic lens which focuses the electrons leaving the filament The anode (A) is connected directly to the body of the machine and is at earth potential. The condenser lens (C) concentrates the beam of electrons emerging from the central aperture in the

ment. Thus the beam of electrons emitted from the hot filament pass through the electromagnetic condenser lens, and strike the object at uniform speed, whereupon a very few are collected by the specimen, and the bulk is scattered at different angles and varying velocities. Electrons which succeed in passing through the object or near to it without loss of speed are brought to focus on the sensitized photographic emulsion. Dark areas in the final positive print so indicate the existence of matter which has scattered electrons away from the path of the beam

Varying depth of shadows seen in different objects are caused by parallel rays which fall on the object and are scattered to different extents, varying in proportion to the "mass thickness" (i e, density × irradiated thickness) of the object. The greater the mass thickness, the greater is the amount of scattering and the

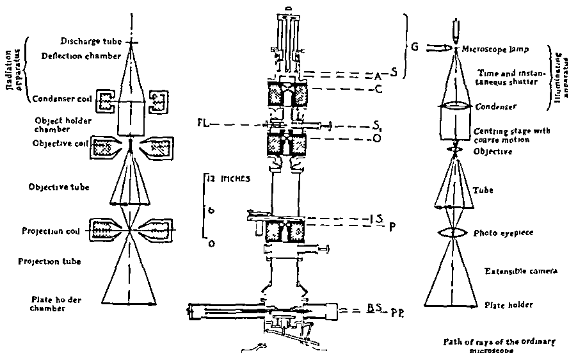

FIG 9 The central diagram illustrates the component parts of the electron microscope built at the University of Toronto in 1944 by Professor Burton and his colleagues (Reproduced from Burton, E F, and Kohl, W. H, *The Electron Microscope*, Reinhold, 1946) The lateral diagrams are reproduced from the earlier description of von Borries *et al* (1938).

(Reproduced from *Klin Wschr*, 1938, *17*, 921.)

darker becomes the picture. The more widely scattered rays are eliminated by not allowing them to pass through the minute aperture of the objective lens. Parts of the object having a greater mass thickness therefore appear darker than those having a lesser mass thickness In this manner, the electron-optical picture can reveal the mass distribution in minute objects

Mechanical, Structural, Vacuum and Electrical Data

The two-stage magnetic lens electron microscope designed by Ruska (1934) served as a prototype for many later instruments. The first to be built on the American continent was constructed by Burton, Hillier, and Prebus (1939, 1940) at the University of Toronto Instruments of similar pattern are today manufactured for sale as commercial articles by the Radio Corporation of America, Philips

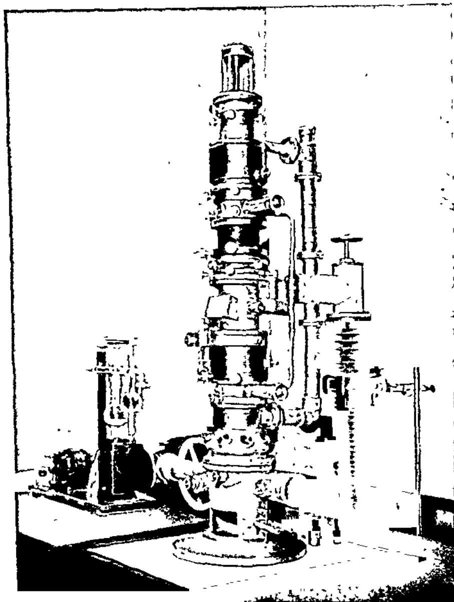

Fig 10 The electron microscope, University of Toronto (1944) type

Industries, Ltd, of Holland, and Metropolitan Vickers, Ltd, of England (Zworykin and Hillier, 1943) Developments continued at the Department of Physics, Toronto University, and Drs Newman and Watson evolved a much improved machine, component parts of which are illustrated in Figs 9–10 Details are as follows Within the electron gun (G) is a tungsten filament, (S) the cathode shield is at the same potential as the filament and produces an electrostatic lens which focuses the electrons leaving the filament The anode (A) is connected directly to the body of the machine and is at earth potential. The condenser lens (C) concentrates the beam of electrons emerging from the central aperture in the

anode so as to focus them upon or just above the object specimen. Incorporated inside the condenser lens is a diaphragm with aperture of 0 5 mm that restricts the maximum angle or semi-angle of the cone of electrons descending upon the specimen. (PL) Plunger for lifting and drawing out the object cartridge. (S,) Object air lock seal. (O) Objective lens and (I.S) intermediate fluorescent screen. (P) Projector lens (B S.) Lower fluorescent screen. (P.P) Photographic plate of 2 × 10 inch size, accommodating six exposures of 1½ × 2 inches on each plate.

For optimum results accurate alignment of lenses, object, carriers, and photographic equipment is imperative, and the microscope should be insulated against all external sources of vibration A high vacuum below 10^{-5} mm of mercury is maintained with an oil diffusion pump, in order that the mean free path of the electrons shall be greater than the optical path they have to travel A high vacuum is also essential for the avoidance of gas discharges within the electron gun, and it should be attained as soon as possible after each occasion on which the object or photographic plate is changed.

Burton and Kohl (1946) stress the necessity for a high degree of voltage stability for effective operation of the electron microscope. "Since the focal length of a magnetic lens is a function of the electron velocity, and inversely proportional *to the square of the magnetic field strength, it is very important to maintain the* acceleratı [illegible]
as nearly [illegible]
depends c [illegible]
on the current through their windings.

The range of power and stability requirements of the R.C A. model B microscope are as follows

Circuit	*Range*	*Stability (%)*
Acceleration potential	55 KV	0 002
Condenser lens	20–120 MA	0 02
Objective lens	20–130 MA	0 002
Projector lens	25–125 MA	0 004

HIGH ACCELERATION VOLTAGE (400 KV) ELECTRON MICROSCOPE

It has been shown by le Poole (1947) that by increasing the electron beam energy up to 150 KV, the wave length of the electrons is reduced, which results in theoretical increase in the resolving power of the instrument The use of higher voltages would also appear to enhance contrast in biological specimens. Thus contrast is produced by scattering of electrons in the specimen and the degree of scat*tering is proportional to the mass through which the beam passes.*

In their studies on the passage of electrons through thick objects, van Dorsten, Oosterkamp, and le Poole (1947) draw attention to spatial scattering within specimen Consequently, little relationship exists between the direction of departure of electrons from the object and their point of entry Error due to spatial scattering cannot be corrected by employment of larger objective aperture, but the effect can be reduced by use of higher acceleration voltage, with reduction in average angle of scattering and decrease in chromatic *aberration due to fluctuations in* electron velocity, lesser heating effect in the specimen at the same current density and diminished ionization In an experimental instrument constructed by these workers, examination of dense yeast cells at 350 KV revealed greatly enhanced internal structure and detail which was invisible at voltages of 225 to 100 KV

THE ELECTROSTATIC ELECTRON MICROSCOPE

Bachman and Ramo (1943) have described a compact and simplified variety of this instrument possessing a resolving power of 200 A.U., equivalent to ten times

that of the ordinary light microscope. The electron gun and three lenses are fed from a single voltage supply, and the need for complicated voltage stability apparatus in the power unit is thereby eliminated.

The three electrostatic lenses operate in conjunction, and as long as their voltage ratio is not disturbed, their focal lengths remain the same, irrespective of voltage fluctuations. A magnification of ×1000 may be obtained on the fluorescent screen, and this can be further enlarged without loss of definition up to ×7000. The R C A. Console Model (type EMC-1) electrostatic microscope, giving a magnification of ×5800, has been used by Oster and Stanley (1946) for photographing tobacco mosaic virus

The electrostatic type of instrument has not been extensively used for the study of viruses, and its range of usefulness is still to be explored

PRACTICAL APPLICATIONS OF ELECTRON MICROSCOPY

The electron microscope has made important contributions to knowledge of the particulate structure of crystals, chemicals, colloids, cements, textiles, fibers, dusts, metallic smokes, and a host of related substances. A general understanding of these is indispensable for appreciation of its capabilities in the virus field.

Of considerable benefit is the greatly increased depth of focus which permits having top and bottom of an object simultaneously in focus. Stereoscopic pictures can be made of some materials such for example, as carbon particles, by first photographing the object, then tilting it through a small angle, and re-photographing Thereafter the two pictures are mounted and viewed after the manner of an ordinary stereoscopic illustration. The finer surface structure of polished metals, alloys, crystals, and other opaque materials can be investigated by a different technique. A surface replica representing a mold of the surface of the material is prepared by pouring a solution of formvar[1] over the metal under examination, allowing it to solidify, peeling it off, and then photographing In this way, it is possible to obtain a "negative" of the minute surface indentations of the metal which produce sufficient depths in the thickness of the contact side of the formvar

and Peck (1942). For darkfield illumination in electron microscopy, see Levy (1944).]

General Biology

The surface contours of human tooth enamel have been studied by use of *polystyrene-silica impression films,* in which a polystyrene mold of the tooth is made under pressure The tooth is removed, and a thin layer of silica is evaporated onto the mold The polystyrene is dissolved, and the silica "positive" is examined.

[1] Formvar (Grade No 15-95) is a polyvinyl formol plastic compound sold by Shawinigan Products Corporation, New York.

Histology

Even the thinnest sections cut on the ordinary microtome are too coarse to be penetrated at the usual speed of electrons emitted by the accelerating field of 40–60 KV employed in standard equipment. Increased penetration is possible by use of higher velocity electrons, but unfortunately contrast is lost. Burton and Kohl (1946) state that for 60 KV sections should be less than 0.25 μ thick; sections 0.1 μ thick have been prepared of the striated muscle of the cockroach by Richards, Anderson, and Hance (1942). [For constructional details of a suitable microtome and sectioning method, see O'Brien and McKinley (1943), and von Ardenne (1939).]

Bacteria, Rickettsiae, Viruses, and Bacteriophages

The entire range of virus particles from 10 mμ to 250 mμ lie within the limits of resolution of the electron microscope, and much information regarding morphology has already been obtained by this method (see p 17). The rickettsiae of typhus fever have been photographed by Weiss (1943). In the case of bacteria, the electron microscope has revealed cell walls structurally distinct from inner protoplasm, flagella on motile species, differentiation within the inner protoplasm, and in some cases localized nucleoprotein within the cell, which has been interpreted as a nucleus (Mudd and Anderson, 1944). Selective staining of bacterial cells with heavy metals is also possible (Mudd and Anderson, 1942). More recently, the electron microscope has been used very successfully to follow structural changes during sporulation of *Bacillus mycoides*, and subsequent germination of the endospores, by Knaysi and Baker (1947), and Knaysi, Baker, and Hillier (1947). The latter claim to have demonstrated bacterial nuclei in photographs taken at an accelerating potential of 150 KV.

Mounting of Specimens

A delicate supporting membrane is prepared by immersing a 3×1 inch glass slide in a 0.1 per cent. solution of formvar in ethylene dichloride, this is dried in air, and the film is cut into small square segments with the point of a needle Thereafter, the slide is gently immersed in a bowl of distilled water, the film detached from the glass and allowed to float on the surface of the water. Next, the formvar film is transferred from the water and placed on top of a 200-mesh stainless steel or copper mesh screen, measuring about 3 mm in diameter. This can be done without damaging the film by passing a small metal ladle with a hole in the center beneath the floating film, lifting it from the water, and placing it upon the tiny object screen disk which can be conveniently rested upon an upright and projecting end of cylindrical brass rod.

Films may also be prepared from hot xylene solutions of alkathene plastic, a low polymer of ethylene formed at high pressure, which is resistant to organic solvents (Ellis, 1947 *b*).

The copper mesh screen and membrane covered side can now be inoculated with a drop of infected material, with the aid of a fine bore pipette Much will depend on the concentration of bacterial or virus bodies in the inoculum Thus if the material is dilute, it may be permitted to dry, or even reinoculated if necessary
10^{8} particles per c c, if a drop is hemispherical
centrated, excess bacteria and débris should be
water and the use of absorbent blotting paper,
in such a way as to avoid tearing the surface film. After drying, the preparation should be treated with any fixative such as formalin or picric acid When examining bacteria, it is possible to judge the number of organisms dispersed over the surface of the film by placing the metal screen on a microscopical glass slide and viewing it with a dry high power objective, simultaneously the presence of fissures

and flaws in the film can be detected, and imperfect preparations discarded. If it is decided to photograph the preparation untreated, the screen and film are placed in a cylindrical brass holder, inserted in the appropriate chamber of the electron microscope, the door is closed, the air exhausted with the vacuum pump, fields are searched with the fluorescent screen and multiple photographs taken. A closed cell for electron microscopy has been described by Abrams and McBain (1944).

Electron Micrographs of Shadow-Cast Elementary Bodies

Since the electron microscope permits great depth of focus in working, the thickness of minute objects of molecular dimensions can be measured by observing

Fig 11 Elementary bodies of molluscum contagiosum, photographed without shadowcasting, × 29,000

shadows cast when they are coated with an extremely thin layer of metal which lacks distinctive structure, e g, gold, chromium, or uranium deposited obliquely from a point source in vacuum (Williams and Wyckoff, 1944, 1945). These workers subsequently applied the technique to the study of virus elementary bodies with

brilliant results. A collodion (or formvar) membrane supported on a 200-mesh screen was first inoculated with a pure suspension of elementary bodies obtained as free as possible from tissue, debris, and amorphous particulate matter by differential centrifugalization. Taylor *et al.* (1943) recommend the employment of $CaCl_2$-Ringer fluid as suitable for emulsification of sedimented material, and 0·02 p.c. $CaCl_2$ solution for further dilutions. According to Beard (1945), the low scattering power of viruses can be enhanced by increasing contrast with $CaCl_2$ or $MgCl_2$. Separate collodion films were inoculated with one drop of each concentration of virus, allowed to rest for two to five minutes, and the surplus fluid was

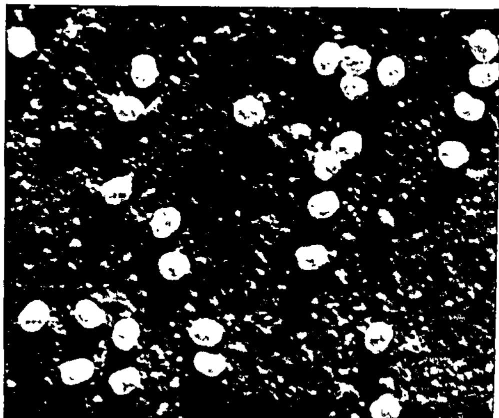

Fig. 12. Elementary bodies of molluscum contagiosum, shadowcast with chromium, × 22,000.

aspirated. After drying, the films and grid object supports were placed in a vacuum chamber, and metal from two hot filaments was evaporated simultaneously at known angles into the specimen. By this means a layer of metal 7 mμ thick can be deposited over the surface of the preparation. The optimum angle at which metallic coating is performed depends on the size of the object, but Williams and Wyckoff (1945) found that for influenza virus (75 mμ) the best angle was that required to make the length of the shadow 5 to 10 times the height of the virus, so that in a successful finished photograph, the elementary bodies should stand out in relief. If accurate height measurements are contemplated, two shadows cast from different directions can be used (see Figs. 11, 12, 13, and 14). Inclusion bodies can also be demonstrated by shadow casting (see Fig. 15 and Boswell, 1947).

Morphology of Viruses

A great number of viruses affecting man, animals, bacteria, and plants have been studied with the electron microscope. Simultaneously, there have been constant improvements in the technique of electron microscopy, the design of instruments and the interpretation and significance of photographic images It should be remembered that when an object is examined with the electron microscope, it is exposed to the effect of a high vacuum as well as slight heating from electronic bombardment, and so a certain amount of shrinkage occurs. It is also possible that other changes may occur in biological matter subjected to prolonged exposure to the

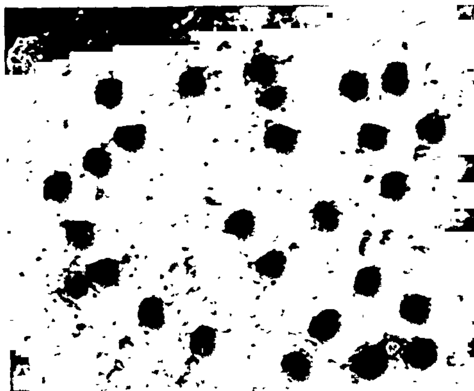

FIG 13. Fowl-pox elementary bodies, shadowcast with chromium, ×20,000.

electron beam Thus, in interpreting the significance of results, a cautious attitude should be adopted, until such time as these expensive instruments are more extensively employed, the results of earlier workers are confirmed, and some degree of standardization is adopted in the selection, manipulation, and mounting of biological material Vaccinia elementary bodies have been photographed, measured, and found to appear as rectangular "brick-shaped" structures occurring in short chains or diploid formation (Green, Anderson, and Smadel, 1942). Likewise, the elementary bodies of molluscum contagiosum, ectromelia, infectious myxoma of the rabbit, and canary-pox present a polyhedral and slightly barrel-shaped outline Ruska and Kausche (1943), and Green, Anderson, and Smadel (1942) found that influenza virus A (PR8 strain) showed a circular outline.

Williams and Wyckoff (1945) estimated that influenza virus A measured 75 mμ, and Mudd and Anderson (1944) reported it to be 100 mμ. Taylor (1944)

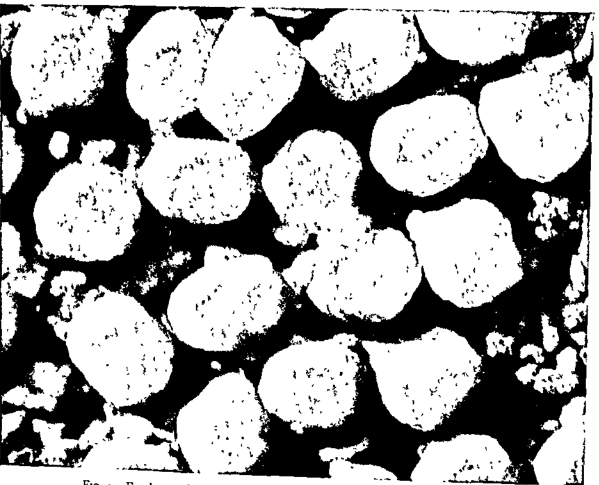

Fig 14 Fowl-pox elementary bodies, shadowcast with chromium, ×80,000.

stated that influenza virus A (PR8 strain) measured 101 mμ, influenza virus B (Lee strain) 123 mμ, and swine influenza virus 96.5 mμ; all were circular in outline Influenza virus B (Lee strain) was said to measure 77.6 mμ by Sharp *et al.* (1944).

Shope papilloma virus was found to be circular in shape and have a mean diameter of 44 0 mμ by Neurath *et al.* (1941). Eastern equine encephalomyelitis virus is spherical in outline and measures 40 2 mμ, according to Taylor, Sharp, Beard, and Beard (1942). The Western variety was photographed at x52,500 diameters and found to be 40 mμ, according to Beard (1945) The virus of New-

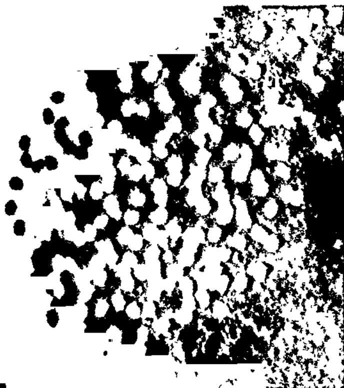

FIG 15. Ectromelia inclusion body, chromium shadowcast, × 12,500

(Figs. 11 to 15 are reproduced by courtesy of Mr. F. W Boswell, M A)

castle disease of poultry has been stated to possess a filamentous phase (Bang, 1947) Normal chick embryo component has been stated to measure 20 mμ (Taylor, Sharp, Beard, and Beard, 1942*a*)

Bacteriophages

Ruska (1941) noticed that when magnified x36 to 41,000, certain types of phage appeared sperm-shaped. Luria, Delbruck, and Anderson (1943) investigated two phages, alpha and gamma, active against *Escherichia coli* Strain B, described earlier by Delbruck and Luria (1942) Virus alpha was found to possess a round head 45–50 mμ in diameter, with a straight or slightly curved tail 150 mμ long and 10–15 mμ thick. Virus gamma showed an oval head 65–80 mμ, a straight tail 120 mμ long and 2 0 mμ thick attached at one pole. It was further noted that each variety multiplied independently on the common bacterial host. Adsorption of

virus alpha on *B. coli* strain B at 37° C. was followed by a pause of 13–17 minutes and lysis of the cell with liberation of about 140 infective units. Gamma virus acting on the same bacterium after an interval of 21–25 minutes, released 135 units per cell. A different coli phage was found to be 50–60 mμ in diameter, without an obvious tail-like appendage. A staphylococcus virus examined was shown to possess a head of 100 mμ in diameter, with a tail 200 mμ in length. The phage particles described were present in amounts proportional to the activity of the material as assayed by plaque counts Furthermore, the structure of the visible particles was found constant for each strain and bacterium exposed. The action of each phage liberated particles morphologically distinctive of the attacking phage.

Luria, Delbrück, and Anderson (1943) also stated that since two unrelated phages were able to parasitize the same bacterial host, it was unlikely that the

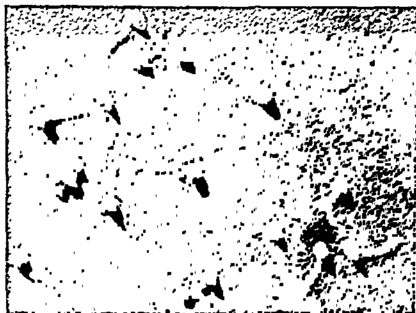

Fig 16 *B megatherium* bacteriophage, shadowcast with chromium, × 40,000
(Reproduced by courtesy of Mr T. A. McLaughlan, M A)

particles freed from the disrupted cell could have been natural protoplasmic components of the bacterium Observations on the same *E coli* gamma (T2) phage, by Hook *et al* (1946), revealed that in crude lysates, the phage resembled a tadpole-shaped particle, with a large head measuring 100×80 mμ, and a short tail 111 mμ by 18 mμ, with knob or disk-shaped extremity An illustration of a B *megatherium* bacteriophage appears in Fig 16 (see McLaughlan, Clark, and Boswell, 1947).

CHAPTER III

THE STAINING OF ELEMENTARY BODIES

Glass Slides

THE VARIETY found most suitable for preparing films of elementary bodies are those made of crystal glass varying from 1 to 1.1 mm in thickness (Coles, 1935). This size suits the working distance of most microscope substage condensers, and consequently slides less than 1 mm or more than 1.3 mm in thickness must not be used unless a specially designed condenser is employed.

mal

met

hours, wash with running water for 24 hours, and store in 50 per cent. alcohol until required, after which they should be wiped and dried with clean gauze. (2) Slides may also be cleaned by boiling them for 15 to 30 minutes in a solution consisting of concentrated sulphuric acid 6 c c, potassium bichromate 6 gm, and water 100 c.c, the liquid being periodically agitated with a glass rod to prevent adhesion of the slides. After removal from the bichromate solution, they should be thoroughly washed in running water for several hours, and then stored in 50 per cent. spirit in an air-tight container.

METHODS FOR THE STAINING OF ELEMENTARY BODIES

The elementary bodies of vaccinia were first demonstrated in stained film preparations made from vesicle fluid by Dr John Buist working at the University of Edinburgh in the year 1886. Buist's observations are of great historical interest, for although he did not recognize the etiological significance of the minute bodies in vesicle fluid, he was undoubtedly the first to have noticed them (Gordon, 1937; Mackie and van Rooyen, 1937).

In a later publication Buist (1887) clearly revealed from an illustration that he not only differentiated these small objects from cocci, but also appreciated the difficulty [illegible] iterest, we ourselves [illegible] by Buist over fifty [illegible] favorably with modern methods

The following is a list of different staining methods which have been found suitable for the demonstration of elementary bodies

Buist's (1887) Method

This is mainly of historical interest, and is carried out as follows

Solution required

Ehrlich-Koch solution consisting of saturated alcoholic solution of methyl violet, 5 to 20 c c, and 100 c c of aniline water consisting of 2 per cent. aniline shaken up with 98 c c of water and filtered

Procedure

1. Cover-glass preparations are made directly from typical vaccine vesicles, and fixed by passing them three times through the flame of a Bunsen burner.
2. Stain for 12 hours in freshly prepared aniline methyl violet solution.
3. If quicker staining is required, then the solution must be gently heated for half to one hour

CHAPTER III

THE STAINING OF ELEMENTARY BODIES

Glass Slides

THE VARIETY found most suitable for preparing films of elementary bodies are those made of crystal glass varying from 1 to 1.1 mm in thickness (Coles, 1935). This size suits the working distance of most microscope substage condensers, and consequently slides less than 1 mm. or more than 1.3 mm. in thickness must not be used unless a specially designed condenser is employed

It is essential that glass slides should be thoroughly cleaned before attempting to make films of material to be stained for elementary bodies, and the following two methods have been recommended. (1) Place the slides in chromic acid for 24 hours, wash with running water for 24 hours, and store in 50 per cent. alcohol until required, after which they should be wiped and dried with clean gauze. (2) Slides may also be cleaned by boiling them for 15 to 30 minutes in a solution consisting of concentrated sulphuric acid 6 c.c., potassium bichromate 6 gm, and water 100 c c., the liquid being periodically agitated with a glass rod to prevent adhesion of the slides. After removal from the bichromate solution, they should be thoroughly washed in running water for several hours, and then stored in 50 per cent. spirit in an air-tight container.

METHODS FOR THE STAINING OF ELEMENTARY BODIES

The elementary bodies of vaccinia were first demonstrated in stained film preparations made from vesicle fluid by Dr John Buist working at the University
istorical interest,
ie minute bodies
(Gordon, 1937,
Mackie and van Rooyen, 1937)

In a later publication Buist (1887) clearly revealed from an illustration that he
not or
culty
selves
fifty
modern methods.

The following is a list of different staining methods which have been found suitable for the demonstration of elementary bodies

Buist's (1887) Method

This is mainly of historical interest, and is carried out as follows

Solution required

Ehrlich-Koch solution consisting of saturated alcoholic solution of methyl violet, 5 to 20 c c, and 100 c c of aniline water consisting of 2 per cent aniline shaken up with 98 c c of water and filtered

Procedure

1 Cover-glass preparations are made directly from typical vaccine vesicles, and fixed by passing them three times through the flame of a Bunsen burner.
2. Stain for 12 hours in freshly prepared aniline methyl violet solution.
3 If quicker staining is required, then the solution must be gently heated for half to one hour

4. Wash in distilled water.
5. Next treat in 60 per cent. alcohol.
6. Dehydrate in absolute alcohol.
7. Mount immediately in balsam and benzol.
8. Contrast staining is usually unnecessary, but if desired, a solution of vesuvin (Bismarck brown) or chrysoidin may be used after washing in 60 per cent alcohol

Paschen's (1906, 1913) Method (see also van Rooyen, 1937)

This method was employed by Paschen for staining the elementary bodies of vaccinia, variola, herpes, varicella, ectromelia, and Shope's fibroma virus, and we have found it to be among the best and most reliable methods for the staining of elementary bodies

Solutions required.

Saturated alcoholic solution of basic fuchsin, 10 c.c., 5 per cent. solution of carbolic acid, 90 c c Alternatively the stain could be made up in two parts: Solution (A) consisting of basic fuchsin, 0 3 gm, ethyl alcohol, 10 c.c., and Solution (B) containing phenol, 5 gm, and distilled water, 95 c c. Mix 1 part (A) and 9 parts (B) and filter before use.

Loffler's flagella mordant. 20 per cent. aqueous solution of tannic acid, 100 c c; ferrous sulphate (saturated solution), 50 c c; basic fuchsin (saturated alcoholic solution), 10 c.c. Allow to stand for several days, and filter before use, mordant improves with age (see von Prowazek, 1912).

Procedure.

1. Make film on slide.
2. Place in distilled water for 3 minutes
3. Dry in air.
4. Fix in absolute alcohol for 5 minutes and treat with ether.
5. Dry in air.
6. Treat with Loffler's mordant and heat gently until steam rises, and allow it to act for 5–10 minutes
7. Wash thoroughly in water
8. Stain with carbol fuchsin solution, gently heating the stain until steam rises for 1 minute, and allow it to remain for a further 10 minutes.
9. Wash rapidly in distilled water and dry with blotting-paper.
10. Mount in neutral mountant or cedar-wood oil

Elementary bodies appear deep red in color when stained by Paschen's method.

The Method of Staining Viruses by Giemsa's (1910) Dilute Solution

This stain has been used by many pioneer workers in their researches on virus diseases Almost every type of elementary body can be stained by this technique, and in skilled hands very beautiful tinctorial effects can be obtained. The stain possesses the advantage of staining red and white corpuscles simultaneously in blood films, but unfortunately it suffers from the drawback of being liable to deposit too readily when standing over a period of time, and moreover different samples of the dye may vary considerably in their staining affinities for elementary bodies (Craigie, 1933) The pH of the tap water used for diluting the stain may also influence the results, if it is unduly acid or alkaline in reaction

Coles's (1935) Method

This is probably one of the best methods of applying Giemsa's stain and has been successfully employed to demonstrate the elementary bodies of vaccinia, herpes, psittacosis, and other virus diseases

Apparatus needed.

A curved glass plate 10 in. long and 4 in. broad, possessing a concave upper surface of about 18 in. in radius of curvature A flat tin box 12 in long, 6½ in broad, and 1 in. deep, fitted with an airtight lid.

Solutions required.

Stain. Giemsa's powder (Grubler), 0 75 gm, glycerine, 25 c c, and industrial methylated spirit, 75 c.c., are thoroughly mixed and well shaken

Differentiating solution. Orange G, 1 gm, tannic acid, 5 gm.; and water, 100 c c.

Procedure.

1. Make thin films as usual.
2. Fix by placing over the mouth of a wide-necked jar—containing crystals of iodine—until the film turns light brown after about ½ to 1 minute exposure (Plimmer, 1913).
3. Treat with absolute alcohol for 5 minutes.
4. To stain, place the film face downward on the curved plate and run underneath it three drops of the stock Giemsa's solution and three drops of methylated *spirit to which is added three times as much tap water.*
5. Place the curved plate in the airtight metal box and allow the stain to act for 24 hours.
6. Renew the stain at the end of the first day and allow it to act for a further 24 hours.
7. Wash the film in tap water, and differentiate it if necessary by placing a drop of the differentiating solution on one end of the film, and allowing it to act for a few moments before washing off with water.
8. Dry the film with blotting-paper, and mount in neutral mounting medium

Hosokawa's Modification of Giemsa's Staining Method

(see Taniguchi *et al*, 1934 *a*)

The elementary bodies of molluscum contagiosum, smallpox, varicella, herpes, zoster, fowl-pox, and rabbit myxomatosis may all be stained by this technique irrespective of whether they occur intracellularly or extracellularly The stained virus bodies appear reddish-purple or bluish-purple We have noticed that Hosokawa's solution has a tendency to overstain the granules of eosinophil polymorphs, and unless the results are carefully controlled, mistakes are liable to occur

Solutions required

Fixative Pure methyl alcohol, 100 c.c, formalin, 5 c c, and glacial acetic acid, 1 c.c

Eosin solution 1 per cent watery eosin solution (Grubler B A.)

Stain Eosin methylene blue, 4 gm, azure I, 0 8 gm, crystal violet, 0 05 gm, these are dissolved in a mixture of methyl alcohol, 250 c c, and glycerine, 250 c c This stock solution is diluted before use (*vide infra*).

Procedure

1. Films are made on glass slides in the ordinary manner, and allowed to dry in air
2. Treat with fixative for 2 minutes, wash in water
3. Flood with eosin solution and heat over a flame until steam rises for half a minute, then wash in water
4. Hosokawa's stain is next applied by adding 1 c c of stock solution to 50 c.c of distilled water, and applying the diluted mixture to the slide for 30 to 40 minutes at room temperature
5. The stain is washed off with water, the slide is dried in air and examined under the microscope

The Taniguchi *et al.* (1934 b) Modification of Giemsa's Method for Staining Elementary Bodies

This method has proved useful for staining the elementary bodies of variola, vaccinia and varicella viruses as well as certain types of cell inclusion.

Solutions required.

Fixative. Pure methyl alcohol, 100 c.c.; formalin, 5 c.c.; glacial acetic acid, 1 c.c.
Stain. 1 per cent. watery eosin-Giemsa solution (Grubler B A.).

Procedure.

1. Make smears and dry thoroughly in air.
2. Fix for 2 minutes in fixative solution.
3. Wash in water.
4. Flood with eosin-Giemsa staining solution and gently warm over flame for ½ minute if staining vaccinia or variola virus, and for 1 minute if films of chickenpox or herpes virus are being treated
5. Wash with water, dry, and examine. Elementary bodies stain bluish-purple.

Craigie's (1933) Method

Solutions required.

(*a*) A 2 per cent aqueous solution of mercurochrome.

(*b*) The stain employed has the following composition: 2 per cent. aqueous solution mercurochrome, 220 Soluble (H.W. & D.), 1 c.c., 7 per cent. aqueous solution M/5 Na_2HPO_4, $2H_2O$ (or Na_2HPO_4, $12H_2O$), 5 c.c.; 1 per cent aqueous solution methylene azure (azur I) (certification No NAz4), 1 c.c., 1 per cent. aqueous solution methylene blue (U.S.P. med.) (certification No NA5), 25 c.c.; and distilled water, 75 c.c.

The constituents are added in the order stated and the mixture, which should not be filtered, retains its staining qualities unimpaired at room temperature for three months

Procedure.

1. Spread films very thinly as in preparing a blood film when working with preparations derived from the skin, tissue scrapings should be suspended in distilled water before films are made.
2. Wash in two changes of distilled water for 5 minutes, dry
3. Fix in methyl alcohol for 5 to 10 minutes, dry.
4. Rinse in distilled water and shake or blot off excess water. Cover film with 6 drops of 2 per cent aqueous mercurochrome for 5 to 10 minutes Rinse rapidly in tap water and later in distilled water, blot off excess water
5. Cover film with stain (6 drops) for 5 to 10 minutes.
6. Rinse off stain as rapidly as possible and blot and dry immediately or, alternatively, simply blot and dry without rinsing. The only part of the technique which requires care is the final step of removing the stain and drying the film, since water, if left in contact with the stained film, tends to dissolve out the dye from the elementary bodies Hence it is necessary to dry the preparation as quickly as possible Elementary bodies stain bluish-purple

Herzberg's (1934) Victoria Blue Stain (Ordinary Method)

Victoria blue was first shown by von Prowazek (in 1905) to be a suitable dye for the staining of elementary bodies of vaccinia. With it the elementary bodies of vaccinia, varicella, herpes, and canary-pox have been demonstrated in smears prepared from infective tissue. Herzberg (1936) has also been successful in detecting

the individual differences in size exhibited by these viruses when compared with one another under the microscope. When stained by this method the individual elementary bodies appear dark blue in color and the dye shows little affinity for staining the cell cytoplasm

Solution required.

The *stain* is prepared as follows 9 gm of Victoria blue 4 R. (Bayer) are dissolved in 300 c c. of distilled water, heated to 60° C. for 30 minutes, placed in a brown-colored bottle for 14 days, and filtered before use

Procedure.

The procedure employed for staining elementary bodies of different virus diseases varies slightly and may be summarized as follows

Vaccinia. Films are made from infected corneal tissue 3 to 4 days after infection, dried in air for 24 hours, placed in distilled water for 10 minutes, dried at 37° C. for 1 hour, stained with 3 per cent. Victoria blue solution for 5 minutes, rinsed with distilled water, dried, and examined (See also Haagen and Kodama, 1934).

Varicella. Thin films are made from vesicle fluid, dried in air for 24 hours, stained with Victoria blue solution for 20 minutes, washed with distilled water, and examined under the microscope.

Herpes. Impression preparations are made from infected rabbit cornea, dried for 24 hours in air, placed vertically in a jar of distilled water for 10 minutes, dried at 37° C for 1 hour, stained with Victoria blue for 30 minutes, rinsed in water, dried, and examined.

Ectromelia Films are made from the feet of infected mice, dried for 24 hours, stained for 10 to 30 minutes, rinsed in distilled water, dried, and examined.

Canary-pox Films are made from infected tissue, stained for 5 minutes, washed in distilled water for 30 seconds using two changes until clear, dried, and examined.

Herzberg's (1934) Victoria Blue Contrast Staining Method

This has been used for demonstrating the elementary bodies of vaccinia and canary-pox, and is carried out as follows

Solutions required

(*a*) *Nuclear red*[1] 5 gm. of aluminium hydroxide are melted in 100 c.c. of hot distilled water, filtered through paper, 0 1 gm of nuclear red added, dissolved by boiling, again filtered, and 0.5 c.c of a 10 per cent. solution of acetic acid added

(*b*) *Light green*[1] 1 gm of the dye is dissolved in 100 c c of distilled water, and 0 5 c c of 10 per cent acetic acid solution is then added

(*c*) *Victoria blue* A 0 1 per cent solution of Victoria blue 4 R solution is prepared by diluting the 3 per cent stock stain already described, to this is added 0 5 c c of 10 per cent acetic acid

Procedure

1 Films are prepared as usual
2 Place in distilled water for 10 minutes
3 Dry in air for 1 hour
4. Treat with nuclear red solution for 15 minutes.
5. Rinse for 30 seconds in distilled water using two changes.
6 Dry in air for 30 minutes
7 Treat with 1 per cent light green solution for 2 minutes.

[1] Hollborn (Leipzig) standard stains

8. Wash with distilled water for 5 seconds, twice.
9. Treat with 10 per cent. tartaric acid for 3 minutes.
10. Wash twice in distilled water for 5 seconds each time.
11. *Stain with 0.1 per cent. Victoria blue solution for 20 seconds.*
12. Wash twice in distilled water as before.
13. Dry in air and examine under the microscope.

Gutstein's (1937) Methyl Violet Stain

This stain has been used for staining vaccinial and other elementary bodies.

Solutions required.

(*a*) *1 per cent methyl violet in distilled water.*
(*b*) 2 per cent. sodium carbonate.

Procedure.

Clean slides in nitric acid, and rinse with alcohol-ether.

1. Prepare films, dry in air or incubator. If much protein is present rinse first in saline, and then in distilled water.
2. Fix film in methyl alcohol for half an hour or more, and place the slide in a dry Petri dish.
3. Mix equal parts of solutions (*a*) and (*b*) in a test-tube, filter immediately on to slide, cover the dish with a lid, and incubate it at 37° C. for 20 to 30 minutes.
4. Rinse in distilled water.
5. Dry in air, mount in cedar-wood oil or liquid paraffin When seen under the microscope, elementary bodies stain light violet

The above staining procedure can be shortened by fixing the film by gentle flaming, pouring the filtered mixture of (*a*) and (*b*) on the slide, and slowly heating it over a Bunsen burner until steam rises. After 3 to 5 minutes, the slide should be washed with water, dried, mounted, and examined in the usual way.

Gutstein's (1937) Modification of Herzberg's Victoria Blue Stain

Solutions required.

(*a*) Victoria blue 4R, 1 gm, alcohol, 10 c.c., and distilled water, 90 c.c.
(*b*) 0.02 per cent potassium hydroxide in water.

Procedure.

1. Invert the film and place the slide face downward on two supporting pieces of capillary tubing placed in a Petri dish.
2. Mix equal parts of solutions (*a*) and (*b*) together, filter at once, and run under slide.
3. Cover the Petri dish with a lid and allow it to stand overnight at room temperature
4. Remove and rinse the slide with distilled water.
5. Dry and mount in neutral balsam or paraffin In a well-stained preparation the elementary bodies should stain dark blue

Castañeda's Method (see Zinsser and Bayne-Jones, 1934, also Castañeda, 1930)

This stain is excellent for demonstrating rickettsiae in films of infective tissues, and Bedson (1937) has recommended it for staining psittacosis virus bodies in the spleen of experimentally infected mice

Solutions required.

Buffer. Potassium dihydrogen phosphate (KH_2PO_4), 1 gm., is dissolved in distilled water, 100 c.c., and added to sodium phosphate ($Na_2HPO_4{,}12H_2O$), 25 gm., dissolved in distilled water, 900 c.c. The mixture is adjusted to pH 7.5, and 1 c.c. of formalin is added as a preservative.

Stain. Methylene blue, 1 gm., methyl alcohol, 100 c.c.

Counterstain. 0.2 per cent. safranine O[1] in distilled water, 1 part; and 0.1 per cent. acetic acid, 3 parts.

Procedure.

1. Spread very thin films of the material on clean glass slides.
2. Stain for 3 minutes with a mixture consisting of 20 c.c. of buffer solution, 1 c.c. of formalin; and 0.15 c.c. of stain.
3. Pour the stain off the slide without washing.
4. Treat with counterstain for 1 to 4 seconds (never more than 5 seconds).
5. Wash with tap water, dry, and examine. Elementary bodies stain deep blue.

Bedson and Bland's Modification of Castañeda's Stain
(see Bedson, 1937)

This method has been employed for staining psittacosis virus particles.

Solutions required.

Stain. This is a mixture composed of phosphate buffer solution (pH 7.0), 95 c.c., neutral formalin, 5 c.c., and borrel blue, 10 c.c.

Counterstain. A 1 per cent. aqueous solution of safranine is employed.

Procedure.

1. Smears or impression preparations are made on clean slides.
2. Fix with methyl alcohol.
3. Treat for 2 minutes with staining solution.
4. Wash with tap water.
5. Counterstain for a few seconds, and dry with blotting paper.

Lépine's Modification of Castañeda's Method

Solutions required.

Stain. A stock solution of stain is prepared by dissolving azure II (Grubler or Gurr) to make a 1 per cent. solution in 0.5 per cent. phenol in water, this is diluted before use by adding 10 drops of the solution to a second mixture consisting of 10 c.c. of distilled water, 10 drops of neutral formalin, and 5 drops of 1 per cent. potassium carbonate. This mixture is heated before being applied to the film.

Counterstain. This consists of safranine diluted 1 in 2,000 in distilled water.

Procedure.

1. Films are made and fixed after the manner described above.
2. Stain with hot solution for 5 to 10 minutes.
3. Wash in tap water.
4. Counterstain with safranine for 5 to 10 seconds.
5. Wash in tap water and dry with blotting paper.

Bedson (1937) has particularly recommended this method, which stains psittacosis E. B.'s deep blue.

[1] National Aniline and Chemical Co., New York.

Six Methods Described by Taniguchi *et al.* (1932) for Staining the Elementary Bodies of Variola

Method one.

Solutions required.

(*a*) Pure acetone.
(*b*) *Mordant.* Add 1 per cent. cadmium iodide to neutral concentrated liquid formalin; the yellow precipitate which is formed is next redissolved by adding the minimum quantity of concentrated hydrochloric acid.
(*c*) Eosin, 0.2 gm., and alcohol, 10 c.c., are mixed together with 5 c.c. of concentrated formalin to which distilled water is added up to 200 c.c., so as to make an orange-red colored solution free from turbidity.
(*d*) Carbol fuchsin solution

Procedure.

1. Thin films are made and allowed to dry in air for 1 to 7 days before staining.
2. Treat with acetone for 1 minute, wash slowly.
3. Mordant with formalin solution for 1½ to 2 minutes; wash with water.
4. Stain with carbol fuchsin solution for a few seconds, wash with water, dry, and examine.

Method two.

Solutions required

(*a*) Sodium hydroxide, 0.5 gm., sodium carbonate, 0.5 gm., and distilled water, 10 c.c., are mixed together, absolute alcohol is added up to 100 c.c.
(*b*) Pure sulphuric acid, 2 c.c., water, 10 c.c., and absolute alcohol up to 100 c.c. are mixed together.
(*c*) Zinc or cadmium iodide, 5 gm., and iodine, 0.5 gm., are dissolved in absolute alcohol, 100 c.c.
(*d*) 1 per cent. aqueous solution of eosin.
(*e*) Ziehl-Neelsen's carbol fuchsin solution.
(*f*) Acetone.

Procedure.

1. Place in reagent (*a*) for 1 minute, wash in water.
2. Place in reagent (*b*) for 1 minute, do not wash in water
3. Mordant in (*c*) for 1 minute, wash in water
4. Treat with eosin solution (*d*) for 30 seconds, wash in water
5. Stain in (*e*) for a few seconds, wash in water.
6. Differentiate in acetone for a few seconds, wash, dry, and examine

The Paschen bodies of smallpox stain pink by this method.

Method three.

Solutions required

(*a*) Sublimate alcohol solution consisting of absolute alcohol, 30 c.c., mercuric chloride, 4 gm., and distilled water, 60 c.c.
(*b*) This consists of a solution of alcohol to which a trace of iodine has been added.
(*c*) 0.25 per cent. sodium thiosulphate solution
(*d*) 2.5 per cent. iron alum solution
(*e*) Heidenhain's iron hematoxylin solution

Procedure.

1. Place in sublimate-alcohol at 60° C for 3 hours, wash in water for 5 minutes.
2. Treat with iodine alcohol for 5 minutes; wash with water for 5 minutes
3. Treat with sodium thiosulphate for 10 minutes, wash in water for 5 minutes.
4. Stain in Heidenhain's iron hematoxylin solution for 24 hours.
5. Differentiate in iron alum.

The elementary bodies appear grayish-blue in color.

Method four.

Solutions required.

(*a*), (*b*), and (*c*) as in Method three.
(*d*) Either acid fuchsin solution is used consisting of 10 per cent. acid fuchsin containing 5 per cent carbolic acid, or else 2 per cent aqueous fuchsin containing 1 per cent. sulphuric acid is necessary.
(*e*) Alcoholic solution of picric acid

Procedure.

1, 2, and 3 as in Method three.
4. Flood the slide with acid fuchsin and heat until the steam rises, allow to cool and repeat.
5. Differentiate in an alcoholic solution of picric acid.

The elementary bodies stain reddish-violet.

Method five (Gram's stain applied to elementary bodies).

Procedure

1. Fix film in ether-alcohol for 20 minutes, wash with water.
2. S[illegible]
3. D[illegible]

Elen[illegible]

Method six.

Solutions required.

(*a*) Sodium hydroxide, 0 5 gm, and sodium carbonate, 0 5 gm, are added to 10 c.c. of distilled water, the total volume is made up to 100 c.c. by addition of absolute alcohol.
(*b*) Pure sulphuric acid, 2 c c, is mixed with 10 c c. of water, absolute alcohol is added up to 100 c c
(*c*) Zinc or cadmium iodide, 5 gm, and iodine, 0 5 gm, are dissolved in 100 c c. of absolute alcohol
(*d*) Carbol methyl violet solution (Gram).
(*e*) Lugol's iodine (Gram)

Procedure.

1. Thin films are made on clean slides and allowed to dry in air for 24 to 48 hours
2. Treat with solution (*a*) for 1 minute, wash in water.
3. Treat with solution (*b*) for 1 minute, do not wash in water
4. Treat with solution (*c*) for 1 minute, wash with water.
5. Stain film with carbol methyl violet for 4 seconds, heat gently until steam rises, wash with water
6. Treat with Lugol's iodine for 30 seconds, wash in water
7. Differentiate with alcohol or acetone, wash with water, dry, and examine.

The elementary bodies stain blue-violet

Goodpasture's (1925) Method

This stain was originally introduced for Negri bodies in sections of rabies material. Subsequently, Goodpasture (1925) modified the stain by the introduction of potassium permanganate solution as a mordant, and employed it for staining the elementary bodies of molluscum contagiosum.

Solutions required.

Stain 20 per cent. alcohol, 100 c.c.; phenol (concentrated and pure) solution, 1 c.c., aniline oil, 1 c.c.; and basic fuchsin, 0 5 gm. The stain should be made up each time before use.

Mordant. 1 per cent. potassium permanganate solution in distilled water is used.

Counterstain. A saturated solution of methylene blue in alcohol, 30 c c., and a 1: 10,000 dilution of potassium hydrate in distilled water, 100 c c.

Procedure.

1. Films should be fixed in Zenker's fluid as the method is nonapplicable to tissues fixed in Helly's fluid.
2. Mordant for 1 minute with potassium permanganate solution, wash thoroughly in water.
3. Stain with carbol-aniline-fuchsin solution for 10 minutes.
4. Wash off the excess stain with water, blot with filter paper, and decolorize with 96 per cent. alcohol until the section or film turns light pink in color.
5. Wash with water, and counterstain for 15 to 60 seconds with Loffler's methylene blue solution.
6. Wash with water, dehydrate, and decolorize for a few seconds in absolute alcohol until the excess of blue is removed.
7. Clear in xylol and mount in balsam.

Morosow's (1926) Modification of Fontana's Method for Staining Elementary Bodies

Solutions required.

Fixative. This consists of acetic acid, 1 c.c., 40 per cent. formalin, 2 c c.; and distilled water, 100 c.c.

Mordant. Carbolic acid saturated solution *Karbolsaure* (see Morosow, 1926), tannin, 5 gm; distilled water, 100 c c

Silver stain. 20 c.c of distilled water plus one drop of 25 per cent. ammonia are placed in a test tube, and a 10 per cent. solution of silver nitrate is added, drop by drop with a pipette, until a brown precipitate appears. The addition of silver nitrate is continued until this precipitate redissolves and the solution turns opalescent.

Procedure.

1. Make a thin film.
2. Dry in air.
3. Place in distilled water for 10 to 15 minutes
4. Dry in air.
5. Treat with fixative for 1 minute
6. Wash with distilled water.
7. Treat with mordant and heat gently for 30 to 60 seconds until the steam rises, but do not allow it to boil
8. Wash thoroughly with distilled water for 30 seconds
9. Add about 0 5 c c. of silver nitrate to the slide and again heat gently for 1 to 2 minutes until the film turns light brown in color
10. Wash thoroughly with distilled water and examine for Paschen bodies

In a well-stained preparation elementary bodies should appear dark brown. In our experience this method has given good results, but we have come to the conclusion that caution is necessary as artefacts simulating virus bodies are liable to be found if the preparation has been overstained. Turevich (1935) has employed silver impregnation methods for staining the elementary bodies of vaccinia

Macchiavello's Stain for Rickettsiae (Zinsser, Fitzpatrick, and Wei, 1938)

Solutions required.

(*a*) 0.25 per cent solution of basic fuchsin made up in buffered phosphate solution of pH 7.4 or distilled water adjusted to pH 7.2–7.4 by addition of sodium hydrate or sodium carbonate.
(*b*) 0.5 per cent. citric acid solution.
(*c*) 1 per cent. aqueous solution methylene blue.

Procedure.

Smear preparations are dried in air, treated with filtered solution (*a*) for 4 minutes, rapidly washed off with solution (*b*) and rinsed in tap water. Treat with (*c*) for 10 minutes, wash with water, dry.

The method has proved valuable for demonstration of extra- and intracellular rickettsiae which stain red.

CHAPTER IV

THE USE OF EARTHENWARE, PORCELAIN, ASBESTOS, AND GLASS FILTERS

ALTHOUGH at the present time collodion membrane filters have superseded others in the study of viruses, so much pioneer work has been done with the earthenware types that we feel a general account of their characteristics not to be out of place.

Types of Filter

The following different types of filter have been used in the study of virus diseases

(*a*) diatomaceous earth or kieselguhr,
(*b*) unglazed porcelain,
(*c*) asbestos,
(*d*) and glass, their individual characters will now be described.

(*a*) Diatomaceous earth filters.

The Berkefeld. This type is made in Germany and is supplied in three grades according to the degree of permeability to water. these are the coarse "Viel," medium "Normal," and fine "Wenig" filters, called the V, N, and W grades, respectively The V grade is the most commonly employed of the three, and should retain *B prodigiosus* at a low pressure, such as 100–200 mm. of mercury, but if the pressure is raised above this limit, then not only *B. prodigiosus* but also *B. influenzae* will pass through (see Dible, 1932). The N type prevents the passage of bacteria, and the W grade retains the larger filtrable viruses but allows the smaller forms to go through.

The physical characters of the Berkefeld candle have been investigated in detail by Kramer (1927) and Mudd (1922) and their findings will be mentioned later.

The Mandler. This American modification of the German Berkefeld filter is manufactured from kieselguhr, asbestos, and plaster of Paris, and is supplied in three sizes which are graduated according to the results of an air-pressure test after immersion in water The "preliminary" size resists a pressure of 2 to 5 lb per square inch, the "regular" 6 to 9 lb., and the "fine" 10 to 16 lb. per square inch. In construction, the Mandler filter is more robust than the Berkefeld variety but has not been extensively used in the study of viruses

The British Berkefeld filter is constructed differently from the above, is very fragile, and is made only in one grade which, according to our own observations, appears to possess about the same degree of porosity as the German Berkefeld V candle. Like the latter, the lower earthenware end of the bougie is cemented to a metal tube, and at this point fractures and leaks are prone to develop if the filter is roughly handled during cleaning

(*b*) Porcelain filters.

The Pasteur-Chamberland type is made in France and has been extensively used in virus research It is constructed of unglazed porcelain consisting of a composition of kaolin and sand, and since the entire candle is made in a single piece free from joints, it possesses a mechanical advantage over the Berkefeld type. The Pasteur-Chamberland filter also possesses the added virtue of being easily cleaned by heating the candle to a high temperature in an electric furnace

Nine different grades of these filters are available, namely the L_1, L_1 *bis*, L_2, L_3, L_5, L_7, L_9, L_{11}, and L_{13} sizes The L_1 is the coarsest filter of the range and the

makers state that it is only intended for clarifying purposes, whereas the L_1 *bis* and L_2 candles retain the larger bacteria but allow the smaller micro-organisms such as, for example, the organism of bovine pleuropneumonia to pass through An excellent summary of the general characters of the Pasteur-Chamberland range of filters is given by Dible (1932).

Galloway and Elford (1931), working with foot-and-mouth disease virus, adversely criticized the value of the Pasteur-Chamberland filters and stated that they found them to be extremely unreliable.

(*c*) **Asbestos filters.**

The Seitz. Several sizes are made, the smallest of which is the most convenient for virus work, and consists of an asbestos disk clamped (at its circumference) between two metal surfaces After each experiment, the disk is discarded and replaced by a fresh one (which can be sterilized by autoclaving). Two grades are supplied, namely the K (coarse) grade, intended for clarification, and the E K (fine) for retaining large bacteria and even small organisms such as *B. prodigiosus* or *Br. melitensis*, provided that the pressure is not raised above 100 mm of mercury. We have used the E K grade and found that the viruses of vaccinia, ectromelia, Shope's rabbit fibroma, infectious myxomatosis of rabbits, and bacteriophage readily pass through The permeability of the Seitz filter can be decreased by inserting two disks into the metal mantle, this should be done if at any time difficulty is experienced in withholding bacteria

(*d*) **Glass filters.**

The frittered glass variety is constructed entirely of glass and possesses certain advantages, but such filters have not been widely used for virus work owing to the ease with which they become clogged. A [illegible] able and the coarsest grade, which is only [illegible] large tissue particles before attempting tc [illegible] perhaps the most useful of the whole range. The efficacy of the filter for clarifying may be improved by spreading a layer of asbestos pulp (made by shredding a Seitz disk and soaking it in saline) over the glass filter-bed surface before adding the material

The finer grades of frittered glass filters are made in a great range of pore sizes and any dimension varying from 250 μ to 0 15 μ can be constructed to order. The manufacturers[1] supply data with each filter, stating the diameter of the largest pore, the average pore, and the filtration speed in c c. of water per minute We have tried one model possessing an average pore diameter of 0 667 μ, the largest pore being 0 91 μ, and with a filtration speed of 50 c c of water in 30 minutes, 1 second, for studies on myxoma virus and found it satisfactory The only disadvantage we have experienced with these filters is that the glass pores soon become clogged unless the material is well diluted before attempting to filter.

The Cleaning of Filter Candles

[illegible] in [illegible] tair [illegible] 2 per cent phenol solution

The Berkefeld type should be cleaned, immediately after use, by forcing a current of water in the reverse direction through the filter pores After washing away most of the large particles which clog the pores of the candle, it should be immersed in a bowl of water containing a 2 per cent solution of "liquor trypsini co" (B P) and left for 24 hours, preferably in an incubator at 37° C The candle should

[1] Schott & Gen, Jena, Germany, and Pyrex

next be thoroughly washed, scrubbed with a brush, tested for patency, dried, wrapped up in Kraft brown paper, and resterilized by boiling.

The Pasteur-Chamberland variety can be cleaned in the same manner, or by placing the candles in a cold electric furnace and gradually heating them to white heat. After half an hour's heating the current is switched off and the candles allowed to cool slowly.

Frittered glass type Before using a new filter, it should be cleaned by sucking water through its pores followed by hot hydrochloric acid and water again, to remove organic matter. The filters are sterilized by first moistening them and then placing them in a cold Koch steamer which should be gradually heated, and after one hour's exposure at 100° C. the steamer should be allowed to cool before removing the filter. After use, the filters can be cleaned by immersing them in hot sulphuric acid to which has been added a mixture of sodium nitrate and sodium perchlorate for a period of 24 hours. Sulphuric acid and sodium bichromate are not recommended for cleaning as they tend to affect the electrical charge of the glass pores (Laug, 1934).

Some Theoretical Considerations Concerning the Process of Filtration through Earthenware Candles

A variety of different factors determines the ability or inability of a particle of fixed size to traverse the pores of an earthenware filter, for example

1 The amount of positive or negative pressure applied.
2 The length of time for which it is exerted
3 The viscosity of the material filtered
4. The pH of the fluid in which the tissue is suspended.
5. The number of infective elementary bodies in the suspension
6. The average diameter of the elementary bodies or other infective particles present
7. The electrical charge of the filter and of the material to be filtered
8. The average pore diameter of the filter.

In view of the many factors involved, consideration must be paid to each of these before any virus can be definitely asserted to be filtrable. Special care must also be taken to ensure that the filter candle is free from structural defects such as cracks or flaws.

The Pasteur-Chamberland jointless type of bougie filter is probably the most satisfactory of the earthenware varieties, but it unfortunately suffers from certain serious disadvantages For example, when filtering feebly infective emulsions through such a candle, much of the infective material (elementary bodies) becomes adsorbed and retained in the pores of the candle Thus the filtrate may be inactive, even though the average pore diameter of the filter may be many times greater than the size of the virus These remarks are applicable to the Berkefeld candle and, perhaps to a lesser extent, the Seitz asbestos disk

The adsorptive action of earthenware filter candles on viruses can be demonstrated by the following experiment Prepare a series of five decimal dilutions of desiccated rabbit's testis, infected with vaccinia virus, in saline, ranging from 1 1,000 to 1 10,000,000, and inoculate 0 2 c c of each dilution into the shaved skin of a rabbit Make up about 25 c c of a 1 100 dilution of the same tissue, pass it through a Berkefeld V filter, prepare a second series of decimal dilutions of the filtrate, ranging from 1 1,000 to 1 10,000,000, and inoculate 0 2 c c of each as previously into the skin of the rabbit, alongside the first series Examine the animal daily and note the sequence in which vaccinial papules develop, and by comparing the skin reactions produced by each set of dilutions the loss of infectivity of the filtrate due to adsorption will become evident Much will depend on the individual factors prevailing at the time of performing the experiment, but on one occasion

we observed that, whereas 0·2 c.c. of a 1:1,000,000 dilution of (unfiltered) virus emulsion produced a reaction, the same suspension after filtration only reacted up to 1:100 dilution. In another experiment on Shope's rabbit fibroma virus, the filtrate proved to be completely inactive, although the elementary bodies are no larger than those of vaccinia virus. On the other hand, we have observed that ectromelia virus, which is the same size as vaccinia virus (Elford, 1933), traverses the Berkefeld filter with far greater ease. The question thus arises as to what are these differences attributable, and in discussing this problem, Galloway and Elford (1931) have suggested that the activity of a filtrate is governed by the relative number of elementary bodies present in the tissue emulsion before filtration. Thus the greater the number of elementary bodies in the suspension, the more infective the filtrate will be.

It is also probable that a second factor may be the virulence or pathogenicity of the individual virus particles for the species of animal inoculated For example, the British domestic rabbit is highly susceptible to infection with rabbit myxoma virus, less susceptible to vaccinial infection, and comparatively resistant to Shope's fibroma virus, so that if a rabbit were to be inoculated with a filtrate of one of these agents then the result would depend on the number of elementary bodies in the filtrate To quote a hypothetical instance, the minimum infective dose of Shope's fibroma virus may be 50 elementary bodies, that of vaccinia 10, whereas only 1 elementary body of myxoma virus may suffice to infect a rabbit. The inactive filtrates obtained on passing Shope's fibroma virus through an earthenware candle may, therefore, have been due partly to loss of elementary bodies during filtration, and partly to the natural resistance of the British domestic rabbit to infection with this virus Before it is possible, then, to assess the results and relative significance of filtration experiments with earthenware filters, it is necessary to consider the susceptibility of the test animal to infection, in addition to taking into account the other factors enumerated

The Berkefeld filter is made of diatomaceous earth or a compound of silicic acid and carries an electronegative charge. Mudd (1922) has shown that the pores of the Berkefeld candle are the site of an electrical potential difference consisting of a Helmholtz double layer, in which the wall of the filter is negatively charged and the liquid within positively charged When suspensions of tissue are passed through the pores of such a candle, positively charged particles contained in the material become adsorbed and retained by the filter. Consequently all filters constructed of siliceous material, sand, porcelain, powdered glass, colloidal silica, or diatomaceous earth will adsorb basic dyes but allow acid dyes to pass through Thus Victoria blue, which is a basic dye, will not pass the Berkefeld candle, but [illegible]

will not do so Should, however, the Congo red be diluted and made acid (following which it turns blue), then it will pass the plaster of Paris filter but not the Berkefeld variety Thus by reversing the electrical charge, Kramer succeeded in reversing the filtrability of a dye It was also found that if a filter was constructed of both plaster of Paris and diatomaceous earth, it acquired a neutral charge and permitted both positively and negatively charged dyes to pass its walls The behavior of dyes when subjected to filtration through earthenware candles is similar to that exhibited by positively or negatively charged colloids and viruses, and thus Kramer (1927) found that a *Staphylococcus* bacteriophage would pass through a Berkefeld filter but not through one constructed of plaster of Paris, the same applies to vaccinia, rabies, and tobacco mosaic viruses which are negatively charged Likewise, diphtheria toxin behaves in a similar manner, but tetanus toxin, which is electropositively charged, is adsorbed by the negatively charged Berkefeld filter, although each filter adsorbs only a small quantity of toxin Apart from the

influence exerted by the charge of the filter candle over the transit of a small particle through its pores, another factor which plays an important role is the reaction of the fluid in which the virus is suspended. Many interesting observations have been reported on this subject, and it has been shown that substances which are normally retained by a filter can be made to pass through it by preliminary treatment of the candle with oil, egg white, peptone, or heated serum (see Muir and Browning, 1908–9, Holderer, 1912). For example, according to Grinnell (1929), Victoria blue B which normally does not pass the Berkefeld filter can be induced to go through it if the dye is suspended in hormone broth. Results analogous to the behavior of dyes and other substances have been reported in connection with viruses For example, Ward (1929) has shown that the most active filtrates of vaccinia virus were obtained after emulsifying the vaccinial pulp in hormone broth of pH 7.6, and Ward and Tang (1929) demonstrated that vaccinia and herpes "encephalitis" virus were more easily filtrable when emulsified in hormone broth than in normal saline. Bronfenbrenner (1927) discovered that, if particles carrying a bacteriophage were deposited on a Berkefeld filter, the phage could be washed through the candle with broth, but not with water.

Sawyer and Frobisher (1929) reported that yellow fever virus was able to pass through the Berkefeld N candle when suspended in broth, but not if the infected tissues were emulsified in physiological saline. Foot-and-mouth virus has also been shown to have an optimum filtration range lying between pH 6.4 and 8.75 (see Galloway and Elford, 1931).

These findings suggest that suspensions for filtration should be prepared in broth and made alkaline before attempting to filter them through earthenware candles. The opposite opinion to this has been expressed by Green and Eagles (1931), who filtered large quantities of vaccinia virus through Berkefeld V, N, and British Berkefeld filters, and found that the hormone broth was not superior to distilled water as a diluent. They also maintained that the pH of the virus material did not seem to be important within the range pH 6.4 to 8.4. Furthermore, the lining of filters with egg white did not, in their opinion, enhance filtrability of the virus.

Practical Considerations

Owing to the loss of virus resulting from adsorption during filtration through earthenware candles, the material to be filtered should possess an initial high degree of infectivity At the same time, the concentration of tissue protein should be low and any large tissue particles in the suspension, liable to clog the pores of the filter, should be eliminated by preliminary centrifugation at 3,000 r p m. for half an hour, followed by filtration through coarse asbestos pulp similar to that employed by Laidlaw *et al* (1935) in their studies on the influenza virus These workers freed emulsions of lung tissue from excess organic matter by first passing the extracts through sterile asbestos pulp spread over the surface of a coarse-grade frittered glass filter, after which the material was diluted in saline and filtered through a collodion membrane When using Elford's membranes, only a very low pressure, e g, from 20 to 50 cm of mercury, is required for filtration, with earthenware or Seitz filters a higher pressure is demanded, and this may be applied as positive force on the surface of the tissue extract, or by creating a partial vacuum inside the filter flask The latter is more often used and the "negative pressure" applied should be as low as possible, free from fluctuation, and never exceed 30 cm of mercury if possible The time occupied in filtration, the volume filtered, the temperature of the room, and the prevailing atmospheric pressure should be recorded with the other experimental data

Having removed the filtrate, at the conclusion of the experiment, the filter candle should be tested for flaws and structural defects. This is done by making a dilute suspension of *B prodigiosus* (a loopful of a 24-hours' culture of the organism

in 20 c.c. of saline solution) and adding it to the mantle. According to Grinnell (1929), an old culture of *B. prodigiosus* should be employed as a young culture sometimes fails to pass through a filter which is permeable to an older growth. The bacillary suspension is next filtered under the same conditions as the virus material, and after about 20 c.c. have passed through, the filtrate is tested for the presence of bacteria by adding 2 c.c. amounts to 6 tubes containing glucose broth which are incubated at 37° C. for a week, 2 c.c. should also be inoculated into Robertson's bullock heart medium (Mackie and McCartney, 1948) and incubated at 37° C. for 3 weeks for evidence of anaerobic organisms. If growth is absent, the candle may be assumed to be free from defects. It is sometimes the practice to filter the virus suspension and *B. prodigiosus* simultaneously and this procedure can be adopted if desired, when filtering feebly infective material, it is advisable to avoid this method, since Levaditi and Nicolau (1923) have demonstrated that rabies, vaccinia and herpes viruses can be wholly adsorbed by larger bodies such as carbon particles.

The Interpretation of Results

If the filter candle retains *B. prodigiosus* and the filtrate proves pathogenic to a susceptible animal, the result may be regarded as evidence in favor of the filtrable nature of the infective agent. The experiment should, however, be repeated, using another filter of the same type, and if similar results are obtained the virus may be concluded to be filtrable. It is also advantageous to ascertain which filters the virus fails to pass, and accordingly candles of different porosity should be tested.

If the filtrate proves to be nonpathogenic on animal inoculation, the test must be repeated several times before abandoning the experiments, and the pressure should be increased as much as possible, short of allowing the control organism (*B. prodigiosus*) to pass through the candle. The infectivity of the filtrate can be concentrated either by spinning it in a high speed centrifuge at 15,000 r.p.m. for one hour, or by diminishing the bulk of the fluid by evaporation from the frozen state.

Should all these measures fail to yield an infective filtrate, then one of two alternatives is possible: either (*a*) the infective agent is too large or else (*b*) it has been completely adsorbed by the pores of the filter.

In conclusion, it may be stated that when employing earthenware, porcelain, and similar types of filter, a positive result is of value provided that the filter has been proved to be efficient, but in the case of a negative result being obtained, it does not necessarily imply that the agent is not filtrable, since adsorption effects produced by these filters are sometimes so powerful that certain viruses, e.g., trachoma, have the greatest difficulty in traversing them.

The introduction of Elford's collodion membrane filters has helped to overcome many of the difficulties referred to in the previous pages, and in recent years their value in the field of virus research has been accorded universal recognition. The collodion membrane filter occupies a class by itself, and is eminently suitable for the filtration of viruses, because, owing to its thinness, there is little loss of infectivity resulting from adsorption of virus in its pores, and the comparative rapidity with which filtration is accomplished renders clogging of its pores less liable to occur in comparison with earthenware candles. Furthermore, collodion membranes can be accurately graded in porosity according to their average pore diameter, so that the size of the virus can be measured from the filtration data. The properties of these filters will be discussed in the following chapter.

CHAPTER V

ELFORD'S COLLODION MEMBRANE FILTERS

THE INTRODUCTION of these filters has greatly advanced the state of our knowledge concerning the relative size of different filtrable viruses, since they have, to a large extent, overcome the undesirable adsorptive effects associated with earthenware filters. The basic principle underlying their construction depends on utilization of *the antagonistic action of amyl alcohol* and acetone, which affects the rate of aggregation of nitrocellulose particles during evaporation while the membrane is in process of formation Thus, whereas individually amyl alcohol and acetone are solvents of nitrocellulose, when present together they tend to coagulate the nitrocellulose, and the alcohol and ether present maintain this gelling tendency. Elford's *ultrafilters have been evolved from a series of systematic studies on the physical* properties of collodion films, during which it was discovered that collodion films exhibited one of two different types of structure Either the membrane showed a coarse microgel appearance, consisting of a microscopically visible structure, or alternatively a finer ultragel composition which could only be seen to be particulate matter when viewed under *the high power magnification of an ultraviolet light* microscope.

Acetic acid and collodion membranes tended to show both the microgel and ultragel construction and were consequently unsuitable for filtration experiments in view of their excessive variability in pore size Alcohol-ether membranes, on the contrary, consisted of the fine ultragel formation, and being of greater uniformity in average pore size, proved more suitable as membranes for the filtration of viruses Elford also investigated the conditions governing the formation of ultragel structure and found that the ultragel structure was consequent upon spontaneous gelation of the collodion prior to the washing process in water, which served to fix the already potentially existing structure. From this information, Elford was able to increase the state of aggregation in nitrocellulose, while the system still retained its gelling properties This was accomplished by incorporating nonvolatile coagulants with the solvents in the collodion, so that, as the solvents evaporated and coagulation commenced, the nitrocellulose became more aggregated. Thus, the individual particle size of the units composing the ultragel tended to become larger, and *synchronously the interstices of the membrane became enlarged, thereby* increasing the permeability of the filter. A number of nonsolvents was tested in order to find the most suitable one for increasing the permeability of the collodion membranes, and water was found to be the best, yielding membranes of good tensile strength The greater the quantity of water added, the more permeable *became* the filter, until finally a maximum volume of 5 per cent. of water produced complete coagulation of the nitrocellulose, yielding comparatively large pores that were only capable of arresting *B prodigiosus.* Decrease in the permeability of the membrane was, on the other hand, produced by the addition of small quantities of ethyl alcohol, methyl alcohol (synthetic), or acetic acid Thus, by incorporation of solvents or nonsolvents in the collodion system, a series of membranes was produced possessing a range of average pore diameters (A.P.D) varying from A P.D. 3 μ to A P.D 10 mμ Such values of A P D. were obtained from observation of the rates of water-flow (R F W) through the membranes and determination of the specific water content (S W C) of each particular grade of membrane

(Elford and Ferry, 1935). The measurements of R.F.W. were carried out by placing a section of membrane between the two limbs of a specially designed U-tube apparatus. In earlier experiments (Elford, 1931) the maximum pore size (M.P.S.) was determined from measurement of the critical air-pressure (C.A.P.)

Notes on the Preparation of Membranes

Workers desirous of making their own membranes are advised to consult Elford's original publications on the subject before attempting to do so (Elford, 1929, 1931, 1933; Elford, Grabar, and Ferry, 1935), as well as the work of Asheshov (1933) and Bechhold (1907, 1908, 1908 *a*). The following notes indicate the general principles on which they are prepared.

Apparatus.

The collodion is poured into a glass cell of special dimensions where it is allowed to evaporate. The cell may be either of the 20 or 40 cm. size. Each cell is constructed of two thick squares of polished plate glass that have been cemented together with egg white, and the upper of these has a circular hole, 20 (or 40) cm. in diameter and 1 cm. deep, bored into it. The glass cell should be placed perfectly horizontal, and its position should be verified with a spirit-level gauge. All apparatus and solutions should attain a uniform temperature before use, and should remain for 1 hour at 22.5° C. prior thereto. Points requiring care are that the volume of the collodion solution should be accurately measured (75 c.c. collodion for a 20 cm. diameter cell), gently poured, and the period of evaporation accurately timed (75 minutes). The degree of humidity of the atmosphere should also be controlled.

Reagents.

Nitrocellulose–Necol collodion No. 365A/9[1] has been principally employed.

As solvents ethyl alcohol, methyl alcohol, ether, glacial acetic acid, acetone, and amyl alcohol are required. These should be chemically pure, according to Elford, Grabar, and Ferry (1935), but Bauer and Hughes (1935) state that reagents of analytical grade are satisfactory without the additional purification recommended by Elford (1931).

With regard to solutions, amyl alcohol and acetic acid are added by volume and the remainder should be prepared on a gravimetric basis. They should be thoroughly mixed by placing them in a mechanical shaker for 4 hours at laboratory temperature before being used. Every procedure should be uniform and constant throughout and only small quantities of material made up at a time.

Nomenclature.

Elford has introduced a notation in order to describe the composition of the different collodion systems employed. Thus "N*a*/40 (*x* *y*)" means Necol collodion containing "*a*" c.c. of amyl alcohol per 40 gm. of Necol (stock), diluted by the addition of "*x*/10" of its own weight of alcohol and "*y* 10" of ether. Any further modification of such a system is denoted as a volume addition per 100 gm. Therefore, N*a*/40 (*x* *y*)+1 per cent. acetic acid means that 1 per cent. of the acid has been added per 100 gm. of the denoted system.

The following data indicate the properties of membranes prepared from N*a*/40 (1 9) systems consisting of "*a*" c.c. of amyl alcohol added to 40 gm. of Necol solution, then diluted with its own weight of a mixture of alcohol and ether in the rates of 1 9 parts by weight.

[1] A standard ether-alcohol collodion of Nobel Chemical Finishes, Ltd., Slough.

Conditions.

These are indicated below (Elford, 1931).

TABLE 1

System	R.F.W.	A.P.S.	C.A.P.	Membrane thickness	Remarks
		μ	lb./sq. in.	mm	
N10/40 (1.9)	11.5	0.80	30	0.31	
" + 0.5% H_2O	13.0	0.87	28	0.31	
" + 1.0% "	17.2	1.0	22	0.32	Conditions
" + 2.0% "	78.0	2.15	12	0.32	Vol. collodion 75 c.c.
" + 0.5% HAc	1.2	0.26	175	0.33	Cell diameter 20 cm.
" + 1.0% "	0.17	0.10	>200	0.35	Temperature 22.5° C.
" + 1.5% "	0.065	0.06	>200	0.36	Evaporation period
" + 5% MeOH	0.75	0.20	180	0.34	75 mins
" + 10% "	0.23	0.114	>200	0.40	
" + 20% "	0.13	0.088	>200	0.45	

From the above it will be observed that a series of membranes ranging from A.P.S. (or A.P.D.) 2.15 μ to 0.06 μ are obtainable.

Summary of procedure.

N10/40 (1.9) parent collodion under the conditions stated yields a membrane ranging from an A.P.D. of 0.65 μ to 0.85 μ. To increase permeability, small amounts of water in quantities of 0.25 per cent. are added so that a maximum A.P.D. of 2 μ is reached when 2 per cent. of water has been added.

To decrease the permeability of the membrane, acetic acid is added and the concentration is increased by 0.5 per cent. each time so that when a total of 2 per cent. acetic acid is reached a membrane of A.P.D. 10 mμ results. The intermediate pore sizes are obtained by varying the evaporation period, and in this way a graded series of membranes ranging in A.P.D. from 3 μ to 10 mμ can be prepared.

Washing of membranes.

This is done in sterile distilled water which is changed thrice daily for a period of 14 days. Alternatively, they may be washed for 4 days in distilled water, 2 days in freshly boiled 20 per cent. alcohol, and a further 4 days in distilled water.

Sterilization and storage.

Membranes can be sterilized either by placing them in cold distilled water, followed by boiling for 1 to 3 hours, or, alternatively, by carrying out some of the later processes of preparation in an ultraviolet light chamber, after which they can be stored in sterile distilled water.

Determination of A.P.D.

Before use, the pore size of each new batch of membranes should be measured by ascertaining the rate of water-flow pressure (R.F.W.) and the specific water content (S.W.C.) of each particular grade of membrane. The following quotation from Elford's (1931) publication describes the method employed for measuring the rate of water-flow.

Rate of flow of water (R.F.W.).

"The time taken for a known volume of distilled water to flow through a membrane of known area and thickness is measured under standard conditions of temperature and pressure. From the data then known it is possible to calculate the rate of flow of water through the particular membrane under certain arbitrarily fixed conditions. By definition

$$\text{R.F.W.} = \text{c.c./sq. cm./min. for} \begin{cases} \text{0.1 mm. membrane thickness.} \\ \text{100 cm. water pressure} \\ \text{20° C. temperature} \end{cases}$$

Formula for calculation

$$R.F.W. = \frac{Vt60 \times 1000}{\pi r^2 TP}, \text{ where } V = \text{vol. water in c.c.}$$

t = membrane thickness in mm.
r = membrane radius in cm.
T = time of flow of vol. V in sec.
P = water pressure producing flow in cm.

$$= K\frac{Vt}{T}, \text{ where } K \text{ is constant for standard conditions of measurement."}$$

Fig. 17 shows the form of cell used for these measurements.

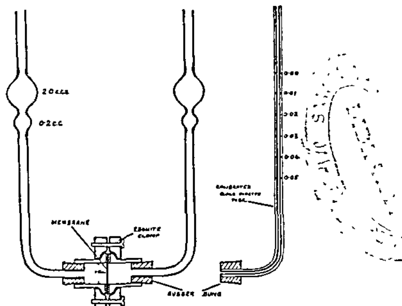

Fig. 17 Diagram showing construction of apparatus for estimating rate of water flow. It can be made by using two glass bottle necks suitably ground with carborundum.

(Reproduced from *J. Path. Bact.*, 1931, *34*, 505.)

For details regarding the estimation of S.W.C. see Elford and Ferry (1935), also Asheshov (1933).

Alternative Method

Elford's work has been successfully repeated by Bauer and Hughes (1935), working in America, who used a collodion product labelled Collodion X660–18.[1] These workers also prepared stock collodion solution, using Du Pont's nitrocellulose parlodion sheets, the exact composition of which was as follows:

Parlodion shreds, 150 gm., absolute alcohol, 250 gm., anhydrous ether, 750 gm., acetone, 1,150 gm., and primary amyl alcohol, 575 c.c.

Before use, parlodion sheets were well washed six times in distilled water, twice in 95 per cent. alcohol, and twice in absolute alcohol, then were used without drying. After the final washing, 250 gm. (316 c.c.) of absolute alcohol, which was freshly prepared by drying 95 per cent. alcohol over lime and distilling, was added to the parlodion shreds which were allowed to swell overnight. On the following

[1] Manufactured by Du Pont De Nemours of Parlin, New Jersey.

day, 750 gm. (1,043 c.c.) of anhydrous ether was added and the mixture shaken at intervals until the parlodion was dissolved. The solution was diluted with its own weight of acetone (1,453 c.c.) and agitated in a mechanical shaker for 2 hours. Primary amyl alcohol was then added in the proportions of 10 c.c. to each 40 gm. of the mixture and the solution again shaken for 2 hours. Finally, the stock preparation was allowed to stand for 2 to 3 weeks before being used. Bauer and Hughes stated that membranes manufactured with such parent collodion gave satisfactory results, and they also drew attention to the fact that the percentage of acetone and amyl alcohol used by them was not the same as that recommended by Elford (1931).

To prepare membranes the stock solution of collodion was diluted with an equal volume of a diluting mixture consisting of 1 part by weight of absolute alcohol and 9 parts of anhydrous ether. This diluted solution was measured in 200 c.c. amounts into a series of 6-ounce bottles fitted with screw caps lined with tin-foil.

Membranes made from such a solution possessed an A.P.D. of 0.6 to 0.8 μ, depending on the humidity and temperature at which evaporation of the solvents occurred. To make more permeable membranes, 2 c.c. of water was added to 200 c.c. of the diluted collodion and this yielded membranes of an A.P.D. 1.0 to 1.2 μ. For preparing membranes below 0.5 μ in A.P.D., glacial acetic acid of analytical quality was added, varying from 0.2 to 3.6 c.c. per 200 c.c. of diluted collodion solution. So many individual factors tended to affect the porosity of the membrane that Bauer and Hughes stated that no definite standards could be laid down, but in general they found that the addition of 1 c.c. of glacial acetic acid to 200 c.c. of collodion solution reduced the A.P.D. to 200 mμ, 2 c.c. reduced it to 100 mμ, and the addition of 3 c.c. reduced the A.P.D. still further to 15 mμ.

Further details were as follows. After addition of the acetic acid or water to the collodion, the mixture was shaken for 2 hours, the solution carefully poured into the cell, the contents of one bottle (200 c.c.) being used for a 40 cm. diameter cell. The optimum evaporation time was found to be 75 minutes, the temperature during evaporation 22° to 24° C., and the relative humidity from 60 to 65 per cent. After evaporation, to remove the membrane, the cell was immersed in water and, without exerting manual traction, the membrane permitted to free itself. The membranes, which were separated from each other by filter paper, were then washed in distilled water for 2 to 3 weeks and placed in a flat photographic developing tray. Disks were cut from the membranes and stored in distilled water in airtight jars; they were calibrated before use according to the method recommended by Elford (1931).

Types of Filter Suitable and Pressure Applied

In a personal communication, Dr. Elford has informed us that two varieties of

Either positive or negative pressure can be used, but when preparing stock filtrates of small amounts less than 20 c.c., or when employing relatively "tight membranes," it is usually more convenient to apply positive force. Thus to prepare a bacteria-free filtrate of a pathological fluid (well-diluted and clarified), a membrane of A.P.D. 700 to 750 mμ should be used, with either a positive or a negative pressure of 25 cm. of mercury.

The Interpretation of the Results of Ultrafiltration

Like other forms of filter, the same factors govern the passage of particles through collodion membranes, but by virtue of their thinness and uniformity of porosity, many of the inherent disadvantages of earthenware filters have been

eliminated The properties of these membranes have been investigated with meticulous care by Elford (1933) who has inquired into the slight effects due to adsorption, variations in the thickness of individual membranes, and the influence of different pressures After consideration of the mode by which each of these individual factors operates Elford (1933) has been able to define the optimum conditions for filtration For example, a 48-hours' old agar culture of *B. prodigiosus* suspended in broth at pH 7 6 was retained by all membranes of pore size less than

0 75 μ. The same effect was demonstrated in the case of the organism of pleuropneumonia, a 3-days' old serum broth culture at 37° C. containing particulate spherical bodies of 0 2 μ to 0 5 μ in size, together with invisible phases below this limit. By filtering the culture through membranes of graded porosity, it was shown that the larger visible spheres failed to pass membranes below 0 35 μ A.P.D., whereas the smaller forms did A membrane of 0 35 μ therefore retained particles of 0 2 to 0 25 μ in size.

It was also pointed out that the concentration of bacteria in the initial bacillary suspension largely determined the number of them which entered the filtrate, an analogous observation was made in the case of foot-and-mouth disease virus by Galloway and Elford (1931). As filtration proceeds the pores of the membrane tend to become progressively clogged, until finally an end-point is reached at which the forces of adsorption and cohesion exert an abnormal effect and slow the rate of filtration The filtration end-point may thus be experimentally ascertained and plotted graphically.

The results obtained with Elford's (1933) membranes showed that the first falling off in maximum filtrate concentration usually occurs at a pore size value varying from two to three times the absolute limiting value for nonfiltrability Fig. 18 shows a graph indicating the filtration characteristics of *B prodigiosus* and vaccinia virus when compared.

The sizes of viruses as determined by ultrafiltration are in close agreement with those ascertained by ultraviolet light photomicrography. For example, ectromelia virus was estimated to measure 0 1 to 0.15 μ by filtration and 0 13 to 0 14 μ by micrometry, according to Barnard and Elford (1931). Likewise, Elford and Andrewes (1932) calculated that the elementary bodies of vaccinia measured 0 125 to 0.175 μ by filtration, and Barnard found them to be 0.17 to 0 18 μ by ultraviolet

Estimation of particle size.

From the results of filtration end-point tests obtained under the optimum experimental conditions, Table 2 indicates the probable size of the smallest particle just retained by a given membrane.

TABLE 2

Membrane *Average pore diameter*	*Size of particle retained*
mμ	
10–100	(0 33–0 5) *d*
100–500	(0 5–0 75) *d*
500–1,000	(0 75–1 0) *d*

d = the average pore diameter of limiting membrane for optimum filtration conditions

day, 750 gm (1,043 c.c.) of anhydrous ether was added and the mixture shaken at intervals until the parlodion was dissolved. The solution was diluted with its own weight of acetone (1,453 c.c.) and agitated in a mechanical shaker for 2 hours Primary amyl alcohol was then added in the proportions of 10 c.c. to each 40 gm. of the mixture and the solution again shaken for 2 hours. Finally, the stock preparation was allowed to stand for 2 to 3 weeks before being used Bauer and Hughes stated that membranes manufactured with such parent collodion gave satisfactory results, and they also drew attention to the fact that the percentage of acetone and amyl alcohol used by them was not the same as that recommended by Elford (1931).

To prepare membranes· the stock solution of collodion was diluted with an equal volume of a diluting mixture consisting of 1 part by weight of absolute alcohol and 9 parts of anhydrous ether. This diluted solution was measured in 200 c c amounts into a series of 6-ounce bottles fitted with screw caps lined with tin-foil.

Membranes made from such a solution possessed an A P.D. of 0 6 to 0 8 μ, depending on the humidity and temperature at which evaporation of the solvents occurred. To make more permeable membranes, 2 c c. of water was added to 200 c.c. of the diluted collodion and this yielded membranes of an A.P D. 1 0 to 1 2 μ. For preparing membranes below 0 5 μ in A.P.D., glacial acetic acid of analytical quality was added, varying from 0 2 to 3 6 c.c. per 200 c.c. of diluted collodion solution So many individual factors tended to affect the porosity of the membrane that Bauer and Hughes stated that no definite standards could be laid down, but in general they found that the addition of 1 c.c. of glacial acetic acid to 200 c c. of collodion solution reduced the A P.D. to 200 mμ, 2 c.c. reduced it to 100 mμ, and the addition of 3 c.c. reduced the A.P.D still further to 15 mμ.

Further details were as follows After addition of the acetic acid or water to the collodion, the mixture was shaken for 2 hours, the solution carefully poured into the cell, the contents of one bottle (200 c c.) being used for a 40 cm. diameter cell. The optimum evaporation time was found to be 75 minutes, the temperature during evaporation 22° to 24° C., and the relative humidity from 60 to 65 per cent After evaporation, to remove the membrane, the cell was immersed in water and, without exerting manual traction, the membrane permitted to free itself The membranes, which were separated from each other by filter paper, were then washed in distilled water for 2 to 3 weeks and placed in a flat photographic developing tray Disks were cut from the membranes and stored in distilled water in airtight jars they were calibrated before use according to the method recommended by Elford (1931).

Types of Filter Suitable and Pressure Applied

In a personal communication, Dr. Elford has informed us that two varieties of instrument are made, the one for positiv
sizes of each type are available, the large
and the smaller which has a capacity of
Either positive or negative pressure can be used, but when preparing stock filtrates of small amounts less than 20 c c., or when employing relatively "tight membranes," it is usually more convenient to apply positive force Thus to prepare a bacteria-free filtrate of a pathological fluid (well-diluted and clarified), a membrane of A.P D. 700 to 750 mμ should be used, with either a positive or a negative pressure of 25 cm of mercury.

The Interpretation of the Results of Ultrafiltration

Like other forms of filter, the same factors govern the passage of particles through collodion membranes, but by virtue of their thinness and uniformity of porosity, many of the inherent disadvantages of earthenware filters have been

eliminated The properties of these membranes have been investigated with meticulous care by Elford (1933) who has inquired into the slight effects due to adsorption, variations in the thickness of individual membranes, and the influence of *different pressures After consideration of the mode by which each of these individual* factors operates Elford (1933) has been able to define the optimum conditions for filtration. For example, a 48-hours' old agar culture of *B. prodigiosus* suspended in broth at pH 7 6 was retained by all membranes of pore size less than 0.75 μ and, *consequently, the average pore size of the limiting membrane furnished* a good indication as to the size of the organism It should be noted, however, that *B. prodigiosus* microscopically varies in size from 0 5 μ to 1 0 μ, so that even those forms which are 0 5 μ fail to pass through a membrane whose average pore size is 0 75 μ *The same effect was demonstrated in the case of the organism of pleuro-*pneumonia, a 3-days' old serum broth culture at 37° C. containing particulate spherical bodies of 0 2 μ to 0 5 μ in size, together with invisible phases below this limit. By filtering the culture through membranes of graded porosity, it was shown *that the larger visible spheres failed to pass membranes below 0 35 μ* A.P.D., whereas the smaller forms did A membrane of 0.35 μ therefore retained particles of 0 2 to 0.25 μ in size.

It was also pointed out that the concentration of bacteria in the initial bacillary suspension largely determined the *number* of them which *entered the filtrate, an* analogous observation was made in the case of foot-and-mouth disease virus by Galloway and Elford (1931) As filtration proceeds the pores of the membrane tend to become progressively clogged, until finally an end-point is reached at which the forces of adsorption and cohesion exert an abnormal effect and slow the rate of filtration The filtration end-point may thus be experimentally ascertained and plotted graphically.

The results obtained with Elford's (1933) membranes showed that the first *falling off in maximum filtrate concentration* usually *occurs at a pore size value* varying from two to three times the absolute limiting value for nonfiltrability. Fig 18 shows a graph indicating the filtration characteristics of *B. prodigiosus* and vaccinia virus when compared

The sizes of viruses as determined by ultrafiltration are in close agreement with those ascertained by ultraviolet light photomicrography. For example, ectromelia virus was estimated to measure 0 1 to 0 15 μ by filtration and 0 13 to 0 14 μ by micrometry, according to Barnard and Elford (1931) Likewise, Elford and Andrewes (1932) calculated that the elementary bodies of vaccinia measured 0.125 to 0 175 μ by filtration, and Barnard found them to be 0 17 to 0.18 μ by ultraviolet light photography. Electron microscopical photographs by Dawson and McFarlane (1948) have shown that vaccinia virus possesses major dimensions of 250 to 200 m μ with ± 5 per cent variation, *and a mean thickness of 110 m μ.*

Estimation of particle size.

From the results of filtration end-point tests obtained under the optimum experimental conditions, Table 2 indicates the probable size of the smallest particle *just retained by a given membrane*

TABLE 2

500–1,000	(0 75–1 0) *d*

d = the average pore diameter *of limiting membrane for optimum filtration conditions*

(Additional details regarding the construction of collodion membranes are dealt with by Elford, Grabar, and Ferry, 1935.) However, Elford (1933) has drawn attention to the fact that the number of particles (e g., *B prodigiosus*) present in a filtrate is dependent upon their concentration in the initial suspension, and Galloway and Elford (1931) have also referred to the same point in connection with foot-and-mouth disease virus This criticism of the value of ultrafiltration as a method for measuring the size of viruses has also been brought forward by Levaditi *et al* (1936), who drew attention to certain pitfalls in the use of ultrafiltration methods. Working with lymphogranuloma inguinale virus, they obtained different sizes for the virus by employing tissue suspensions of varying degrees of pathogenicity. Thus, from filtering a feebly active tissue extract they calculated its size to be 600 to 800 mμ, but by using a more active suspension they found it to be 250 to 350 mμ, and by employing a highly virulent preparation they estimated the size of the virus to measure 100 to 140 mμ. From these observations, it was con-

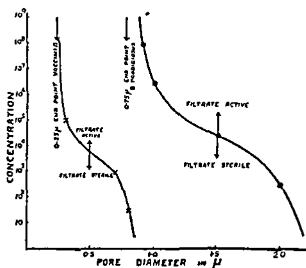

FIG. 18. Graph showing behavior of vaccinia virus and *B prodigiosus* when subjected to ultrafiltration

(Reproduced from *Brit J exp Path*, 1932, *13*, 36)

cluded that the more actively pathogenic was the virus material, the smaller appeared to be its size

Levaditi *et al* (1936) also stressed a second factor liable to influence the results, namely, the susceptibility of the species of animal inoculated with the filtrate when the latter is tested for pathogenicity For example, when filtrates of lymphogranuloma inguinale tissue extracts were injected into a relatively insusceptible animal such as a mouse, they found that the virus appeared to measure 430 to 507 mμ, but if a more susceptible animal such as a monkey was used, then it was found that the virus measured 120 to 180 mμ in size.

Similar deductions were made earlier by Levaditi and Nicolau (1923) in connection with the filtration of neurotropic viruses through collodion sacs The French workers have accordingly concluded that the two factors mentioned have an important bearing on the problem and should be taken into account when measuring the size of viruses by ultrafiltration methods.

These observations are of great interest and suggest that further work on this aspect of ultrafiltration studies is necessary.

CHAPTER VI

THE CENTRIFUGALIZATION OF ELEMENTARY BODIES

In principle, the act of centrifugalizing elementary bodies is no different from that of spinning down bacteria in the ordinary way. A much higher speed is, however, usually demanded, for owing to the smaller size of elementary bodies a greater force is required to deposit them.

The researches of Ledingham (1931) demonstrated that the elementary bodies of fowl-pox (and vaccinia) could be deposited by centrifugalization at 12,000 revolutions per minute (r p m) for 1 hour, after which the supernatant fluid lost its infectivity and the deposited material consisted of innumerable elementary bodies Suspensions of elementary bodies prepared in this manner were agglutinated by specific antisera, and thus their etiological relationship to fowl-pox was proved beyond all doubt. Amies (1934) used the same technique for centrifugalizing the elementary bodies of zoster and varicella, these were obtained by diluting vesicle fluid in 0 86 per cent. saline containing 2 per cent. sodium citrate, centrifugalizing at low speed to throw down tissue cells, and thereafter spinning at 12,000 r p m for 30 minutes to deposit the elementary bodies Such an antigen consisting of a suspension of elementary bodies was used by Amies (1934) for agglutination tests with the sera of patients who had recovered from zoster and varicella infections, respectively.

Both Ledingham and Amies used the bucket type of centrifuge, but other varieties of instrument have also been employed with greater success and some of these are referred to below

TYPES OF CENTRIFUGE

The majority of workers has employed machines of the high-speed type, but Craigie (1932) has shown that they are not essential, since elementary bodies can be deposited at a comparatively low speed provided that the instrument is of the angle design

Centrifuges in common use at the present time may be divided into four classes, namely

1. Those fitted with a *bucket type* of rotating head, driven by a high-speed electric motor such as in the Ecco machine, or by a slower speed motor operating via a geared pulley similar to the old type employed by Ledingham (1931)

2 *The angle centrifuge* This is fitted with a slow-speed motor but is, nevertheless, capable of depositing elementary bodies by virtue of the fact that the construction of the head and the narrowness of the flat glass tube employed compensate for the loss of speed

3. *The Sharples centrifuge* This consists of a cylinder rotating vertically in its long axis at 50,000 r p m into which material is introduced, and propelled by an electric motor, compressed air or steam turbine.

4 *Air-driven instruments* These are based on the principle devised by Henriot and Huguenard (1925), being propelled by a current of compressed air which strikes the slots of an air turbine that can be made to revolve at 60,000 r p m

1. Centrifuges fitted with the Bucket Type of Head and driven by a directly coupled or geared electric motor

The Ecco centrifuge (bucket type).

Both Elford (1936) and we ourselves (van Rooyen and Rhodes, 1937) have used such an instrument This is fitted with a direct drive (d c) electric motor

which revolves at 15,000 r p m and carries four buckets which accommodate hard

(1936) states that the motor attains 4,000 r p m. in under a minute and 10,000 r.p.m. in just over a minute It also slows down quickly and stops within a minute when turning at 4,000 r p m and in one and a half minutes from 10,000 r p m

Measuring the speed of the centrifuge.

By placing a revolution counter or tachometer on the end of the revolving spindle and timing the results with a stopwatch, the speed of the instrument can be calculated At a high speed such as 15,000 r p m this method is probably not the best, for owing to unavoidable losses due to slip and other effects the results tend to be inaccurate Elford (1936) has devised a clever optical contrivance for estimating accurately the speed of the motor, and his description of it is as follows

"A cylindrical tubular extension was attached to the screw cap which fitted the spindle of the centrifuge, projecting about 2 cm. above the top of the metal case. A hole was drilled through this tube at right angles to its axis Light from a pointolite lamp was gathered by a lens and directed as a narrow beam through the hole in the centrifuge extension tube on to the periphery of a toothed disk which could be rotated at a controlled speed The teeth were viewed in a telescope set in alignment with the beam of

r p m The speed of the disk was regulated by means of a potentiometer resistance in series with a small universal motor and was measured by counting the revolutions with the aid of a speedometer and stop-watch In order to embrace the complete range of speeds up to 15,000 r p m two disks each having 72 teeth were coupled by gears in the ratio 1 7 5

"This method enables the speed to be measured without affecting the centrifuge in any way, and is therefore to be preferred to the use of a tachometer."

2. Centrifuges fitted with the Angle Type of Head and driven by directly coupled slow-running electric motor

The ordinary laboratory type of instrument (Bolaget) has been employed by Craigie (1932) The success of this machine depends on the fact that flat glass tubes are used, which possess an internal width of 4 to 5 mm, and consequently the elementary bodies have only to traverse a short distance before they strike the lateral wall of the tube which is placed at an angle of 28° from the vertical With such a centrifuge a speed of 3,500 r p m for 60 minutes was found to be sufficient for depositing the Paschen bodies of vaccinia

An angle centrifuge fitted with a high-speed motor giving a speed of 18,000 r p m and 34–800 times gravity is also obtainable and better results may be expected with this instrument (Pickels, 1942)

3. The Sharples Centrifuge

The closed bowl technique (Schlesinger, 1936)

This ingenious principle makes it possible to obtain a centrifugal force of 20,000 × gravity and provides a quick method of sedimenting viruses To operate the instrument, the inner wall of the rotating cylinder is first coated with a thin layer of agar, which is allowed to solidify, and a small amount of virus suspension is placed inside the cylinder The latter has an internal radius of 2 cm, is 20 cm. high, and revolves at 32,000 r p m Thus when turning at high velocity, the fluid within becomes evenly distributed as a thin film over the surface of the agar, so

CHAPTER VI

THE CENTRIFUGALIZATION OF ELEMENTARY BODIES

In principle, the act of ... lifferent from that of spinning down bacter ... speed is, however, usually demanded, for ... bodies a greater force is required to deposit them.

The researches of Ledingham (1931) demonstrated that the elementary bodies of fowl-pox (and vaccinia) could be deposited by centrifugalization at 12,000 revolutions per minute (r.p.m.) for 1 hour, after which the supernatant fluid lost its infectivity and the deposited material consisted of innumerable elementary bodies. Suspensions of elementary bodies prepared in this manner were agglutinated by specific antisera, and thus their etiological relationship to fowl-pox was proved beyond all doubt. Amies (1934) used the same technique for centrifugalizing the elementary bodies of zoster and varicella, these were obtained by diluting vesicle fluid in 0 86 per cent. saline containing 2 per cent. sodium citrate, centrifugalizing at low speed to throw down tissue cells, and thereafter spinning at 12,000 r p m. for 30 minutes to deposit the elementary bodies. Such an antigen consisting of a suspension of elementary bodies was used by Amies (1934) for agglutination tests with the sera of patients who had recovered from zoster and varicella infections, respectively.

Both Ledingham and Amies used the bucket type of centrifuge, but other varieties of instrument have also been employed with greater success and some of these are referred to below.

TYPES OF CENTRIFUGE

The majority of workers has employed machines of the high-speed type, but Craigie (1932) has shown that they are not essential, since elementary bodies can be deposited at a comparatively low speed provided that the instrument is of the angle design

Centrifuges in common use at the present time may be divided into four classes, namely

1. *Those fitted with a bucket type of rotating head, driven by a high-speed* electric motor such as in the Ecco machine, or by a slower speed motor operating via a geared pulley similar to the old type employed by Ledingham (1931).

2 *The angle centrifuge* This is fitted with a slow-speed motor but is, nevertheless, capable of depositing elementary bodies by virtue of the fact that the construction of the head and the narrowness of the flat glass tube employed compensate for the loss of speed

3. *The Sharples centrifuge* This consists of a cylinder rotating vertically in its long axis at 50,000 r p m into which material is introduced, and propelled by an electric motor, compressed air or steam turbine

4. *Air-driven instruments* These are based on the principle devised by Henriot and Huguenard (1925), being propelled by a current of compressed air which strikes the slots of an air turbine that can be made to revolve at 60,000 r.p m.

1. Centrifuges fitted with the Bucket Type of Head and driven by a directly coupled or geared electric motor

The Ecco centrifuge (bucket type).

Both Elford (1936) and we ourselves (van Rooyen and Rhodes, 1937) have used such an instrument This is fitted with a direct drive (d c) electric motor

The rotor (A) consists of an inverted duralumin cone of 7.6 cm. diameter at its base with a vertex angle of 110°. The top of the base (B) is flat and has four radial recesses cut into it capable of taking four small tubes 2 by 0.5 cm. in size. The tubes are held down during spinning by a flat duralumin disk (C) which is screwed (D) down on the top of the cone. At the foot of the under surface of the rotor a series of cuts or grooves is made and arranged, either in a radial or helicoidal manner, so as to assist the driving force of the air after the principle of an air turbine.

The stator (E). This is a hollow cone made of phosphor bronze provided with nine holes round its interior (I), through which compressed air is forced and allowed to impinge upon the grooves cut into the sides of the rotor cone in an upward and anticlockwise direction. The angle of the stator is 90° to 92°, and the air-holes or jets should be drilled down (F) about 2 cm. from the upper and inner margin of the cone, at an angle of 45° to the axis of the cone when viewed antero-posteriorly and vertically when viewed from the side. The running of the instrument is controlled by an adjustable valve (G), and at the conclusion of the experiment the spinning rotor is lifted off the stator with a metal fork.

Compression plant. To maintain a speed of 60,000 r.p.m., a compressed air plant driven by a 4-h.p. electric motor, and delivering 20 cubic feet per minute at a pressure of 80 to 90 lb. per sq. inch, is required.

Device for estimating speed of centrifuge. McIntosh and Selbie (1937) have used a stroboscope for calculating the speed of their air-driven centrifuge. The method involves fitting up a neon lamp, possessing a frequency of 100 cycles per second, that is worked by an electrically driven tuning-fork yielding a frequency of 6,000 cycles per minute.

A V-shaped mark is made in the revolving top of the centrifuge and the neon lamp is held above it while it spins. When the instrument reaches 6,000 r.p.m. the V-shaped mark appears stationary, and also at each subsequent multiple of 6,000 r.p.m. Thus a speed of 60,000 r.p.m. is reached after the V mark has become stationary ten times. Halves and quarters of these figures can also be calculated, as two V's are visible at half a multiple and four at a quarter of a multiple.

Beams and Pickels (1935) designed an instrument which operated at 100,000 r.p.m., and by the use of hydrogen gas a rotational speed of 1,200,000 r.p.m. was reported earlier by Beams, Pickels, and Weed (1934). Unfortunately, the results of sedimentation experiments with such machines were found to be inaccurate because the thickness of the solution layer had to be limited to 0.1 cm. or less, and undesirable convection currents were introduced through overheating of the rotor (Bauer and Pickels, 1937).

The Svedberg centrifuge.

This is the fastest practical type of centrifuge that has been constructed. The instrument is driven by oil turbines, and a speed of 160,000 r.p.m. has been obtained. The rotor weighs 12.5 gm., the cell 12.9 gm., and for sedimentation measurements up to 900,000 times gravity the two twin turbines operating at each end of the shaft are fed with oil at a pressure of 15 Kg./cm., and during rotation an atmosphere of 20 mm. of hydrogen is maintained. With such an instrument, Svedberg, Boestad, and Eriksson-Quensel (1934) have measured the sedimentation rate of dilute hemoglobin.

Optical ultracentrifuges of the vacuum pattern.

Owing to their great cost of manufacture the oil-driven Svedberg precision centrifuges have been beyond the reach of many virus workers, and less costly machines have been constructed to operate with compressed air power.

Pickels and Beams (1935) devised one of the latter variety, propelled by a compressed air turbine of the spinning-top type, attached by a length of piano

that the virus particles have only a very short distance to traverse before they impinge upon and adhere to the surface of the agar.

The interior of the bowl is coated with agar by first warming the cylinder, introducing melted agar into it, and allowing it to solidify while the cylinder is in motion. For particles less than 20 mμ in diameter 2 per cent. agar is used, and for viruses less than 60 mμ in diameter 1 per cent. agar.

The latest design of the Sharples centrifuge, the Presurtite model, is driven by either compressed air or steam turbine at 50,000 r.p.m. and with a force of 62,000 × gravity. The steam model can be fitted with refrigeration coils to stop overheating. Four sizes of Sharples centrifuge bowls are available, the standard pattern has a volume of 250 c.c. with a layer of residual liquid ¾" deep, and the others have layers of ½", ¼" and ⅛", respectively, with lesser capacity. The highest efficiency is obtained with the ⅛", ¼" and ½" liquid layer bowls, and influenza virus can readily be sedimented without the use of agar lining (Stanley, 1946). Even poliomyelitis virus has been deposited with this type of centrifuge (Melnick, 1946).

4. Air-driven Centrifuges

McIntosh and Selbie's centrifuge.

McIntosh and Selbie (1937) have constructed a high-speed instrument, based on the design of the Henriot-Huguenard (1925) machine, which has no metal bearings and superficially resembles a large humming-top. It is driven by a current

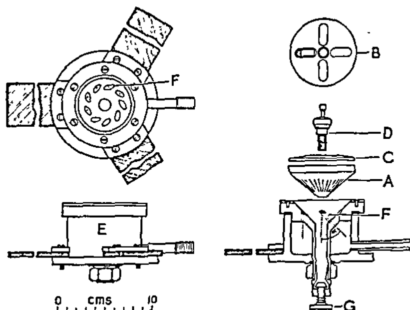

Fig. 19 Sectional diagram showing design of air-driven humming top centrifuge

(Reproduced from *Brit. J. exp. Path.*, 1937, *18*, 162.)

of compressed air which impinges upon the bottom of its outer casing into which a number of slots is cut. The machine therefore revolves on a cushion of air, and any loss of speed arising from friction due to bearings is eliminated. Four small tubes measuring 2 by 0.5 cm. are carried in narrow recesses on the top of the rotor and a speed of 60,000 r.p.m. can be obtained. Fig. 19 indicates the constructional details of the apparatus.

(B). A steel shaft of piano wire 0.100 to 0.110 in. in diameter capable of withstanding 300 to 900 revolutions per second (r.p.s.). For speeds less than 300 r.p.s. a piece of 3/16 in drill rod should be used instead, in order to eliminate vibration

(N). A mild steel conical plate containing a number of holes acting as ports through which air is forced from inlet (M) at 100 lb. per sq in., requisite for a speed of 900 r.p.s. (see Beams and Pickels, 1935).

(L) is the air inlet referred to as the passage for introducing (supporting pressure) air at 30 to 40 lb per sq in used for slow running at 200 r.p.s

(K) and (J) are inlets for oil supplied at a pressure of 5 to 15 lb. per sq in.

g Oil-seal bearing

q. Oil-well.

(r). Oil-drain.

i Conical deflector for oil supply.

e. A short length of rubber pressure tubing

n. Rotor clutch.

c. Rotor made of duralumin alloy 14 S.T., 7 in in diameter, of tapering thickness, being 1 in at periphery and 2 in. at center The outside edge of the cell hole is ½ in from the periphery of the rotor, and the distance between the center of the cell (w) and axis of rotation is 6.5 cm

w. Cell for holding suspension to be centrifuged Is similar to that of Svedberg's. Its main difference is that, being filled from the end during assembly, an oil-seal is unnecessary.

u Dummy cell for balancing rotor

d is the top of the centrifuge housing made of ½ in boiler plate into which the upper of the two quartz glass windows is fitted This is not shown in the sectional diagram The remainder of the rotor is housed in an airtight casing constructed of chrom-vanadium steel, and while it revolves a vacuum of less than 1 mm of mercury is maintained in the chamber by a quick-operating oil pump

The optical system used for [illegible] within the cell during centrifugalizati[illegible] from a mercury vapor arc lamp are r[illegible] lenses, passed through bromine and [illegible] mirror through quartz glass windows placed in the bottom of the vacuum chamber, through the cell (every time the apertures register during rotation), through the top quartz window fitted in (d), reflected by a second aluminum mirror, and finally focused by a 100 cm focal length quartz-fluorite lens upon a photographic plate on which the image is recorded The total distance from the center of the [illegible]

[illegible] used consists of watching a spot placed on the top of the turbine (A) through a slotted disk that is mounted, together with a small magneto, on the shaft of an electric motor The speed of the centrifuge is thus calculated directly in terms of the voltage developed by the magneto At 900 r.p.s (or 60×900 r.p.m.) the centrifugal force at the center of the cell is estimated to be 225,000 times gravity, and at 800 r.p.s (or 48,000 r.p.m.) the force is 180,000 times gravity

Heating during running After some hours of continuous use, the maximum rise of temperature for 800 r.p.s. is found to be 2° C.

Another modification has been introduced by Beams and Black (1939) and Skarstrom and Beams (1940) who replaced compressed air by a high-speed electrical drive, in which the weight of the rotor was supported electromagnetically.

The Size of Viruses Demonstrated by Centrifugalization

The centrifuge designed by Svedberg was fitted with specially constructed windows which allowed optical observations to be made during centrifugation and

wire to the rotor housed in a vacuum chamber. Bauer and Pickels (1936–7) carried out further improvements and successfully sedimented egg albumin at 60,000 r p m. at a centrifugal force of 260,000 times gravity.

Biscoe, Pickels, and Wyckoff's (1936) modification of Svedberg's centrifuge. These workers have designed an air-driven machine with which they have been able to measure optically the sedimentation rate of crystalline proteins of the tobacco mosaic virus. The instrument embodies many of the principles incorporated in Svedberg's centrifuge, and in particular the optical device by which it is possible to watch the sedimentation rate of particles during centrifugalization

The rotor of the machine runs in a vacuum and is enclosed inside an airtight metal casing. Two quartz glass windows are fitted opposite to each other at the top and bottom of this covering, and a beam of ultraviolet light is passed through these so that the progress of sedimentation may be recorded photographically from time to time. For details regarding the fitting of the optical equipment, the reader is referred to the work of Svedberg (1934), Svedberg and Nichols (1927), and Svedberg, Boestad, and Eriksson-Quensel (1934).

Fig. 20 indicates the propelling mechanism of the Biscoe-Pickels-Wyckoff centrifuge seen in cross-section, and its operation is as follows A current of air under pressure enters at either port (L) or (M), passes upward and impinges against

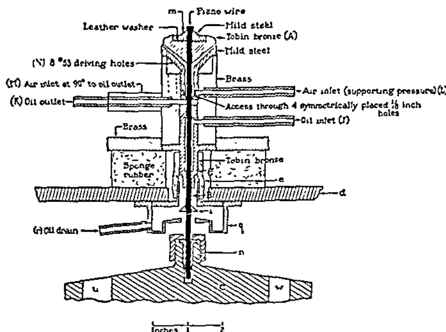

Fig 20 Cross-sectional drawing of the rotating system of the air-driven turbine centrifuge designed by Biscoe, Pickels, and Wyckoff (1936)
(Reproduced from *J exp Med*, 1936, *66*, 39)

grooves cut into the sides of a mobile bronze turbine (A) so that this is set in motion The latter is attached to the rotor (C) of the centrifuge by means of a flexible shaft (B) which revolves simultaneously. Additional constructional details are as follows

(A). Bronze air-driven turbine, the conical surfaces of which have grooves cut into them For details regarding the dimensions, number, and position of these milled flutings, see Beams and Pickels (1935)

m Leather washer acting as a turbine clutch

= initial concentration, and C_t = the concentration after spinning for time t. For conditions such that $C_t/C_0 = 0.1$ this relationship becomes

$$d = k\sqrt{\left(\frac{\eta}{(\sigma_p - \sigma_m)N^2 t}\right)},$$

where $k = 1.78 \times 10^7$ for the metal cells, or 1.84×10^7 for glass cells

By employing this principle for measurement, Elford and Andrewes (1936) found that vaccinia virus measured 170 to 180 mμ, influenza virus 87 to 99 mμ, and the Rous sarcoma virus 60 to 70 mμ.

Elford and Galloway (1937), using this inverted capillary tube technique, found that the size of foot-and-mouth virus was 20 mμ, assuming that the density of the particles was 1.30. Different strains of foot-and-mouth virus appeared to be of the same size and moreover their particles tended to be relatively uniform in dimension.

The size of vesicular stomatitis virus was also measured by the same technique, but its particle size tended to vary and ranged from 74 to 60 mμ, according to whether the density of the particle was assumed to be 1.20 or 1 30, respectively. Subsequent studies by Tang, Elford, and Galloway (1937) showed that equine encephalomyelitis virus measured 39 to 32 mμ, louping-ill virus 27 to 22 mμ, and a *B megatherium* bacteriophage 30 to 37 mμ. The need for more precise knowledge regarding the densities of the particles was emphasized by these workers.

McIntosh and Selbie (1937) carried out similar methods of measurement by using their air-driven centrifuge constructed on the lines of the Henriot and Huguenard (1925) instrument, capable of attaining a speed of 60,000 revolutions per minute. The sedimentation rate of various bodies was expressed graphically to show "a sedimentation angle," and the size of the particle was proved to be proportional to the square root of that angle, i e., $D = K \times \tan\theta$, where D = the diameter of the particle, K = the speed of the centrifuge, and θ = the sedimentation angle.

These workers have used this simple formula for determining the size of virus particles, and have drawn attention to the similarity of their formula to that of Stokes. From their results, they estimated that vaccinia virus measured 99 to 220 mμ from the sedimentation angle, and 103 to 240 mμ from their modification of Stokes' equation.

thus record the rate of sedimentation. Bechhold and Schlesinger (1931) employed the ordinary bucket type of high-speed centrifuge for similar studies, and later Schlesinger (1932) used the same method for calculating the size of viruses and bacteriophages. In his experiments, Schlesinger centrifuged the virus suspension in a wide flat-bottomed tube 5 cm. long and 1 cm. broad, containing at its foot a thick disk of filter paper the purpose of which was to minimize dispersion of the deposited virus particles after centrifugalization. The infectivity-titer of the fluid was first ascertained before centrifugalization (C_0) and later compared with the loss in titer after centrifugalization (C_t), from which he was able to deduce the probable size of the virus particles (*d*) by application of the following formula:

$$d = 6.15 \times 10^{9} \sqrt{\left(\frac{\eta b \log C_0 \times C_t}{(\sigma_p - \sigma_m) R T N^2}\right)},$$

where d = the diameter of the particles in *m*μ, η = *the viscosity of the medium* in C.G.S. units, σ_p = the density of the particle, σ_m = the density of the medium, b = the height of the column of liquid, R = the distance of the filter paper from the axis of rotation, N = the r.p.m. of the centrifuge, and T = the time of centrifugalization in minutes. The above formula has been based on a series of experiments made by Schlesinger (1932) on the size of a range of gold sols of known dimensions.

The specific gravity of a virus is best calculated by centrifuging suspensions made up in varying densities of saccharose solution, to determine the lowest concentration of sugar solution in which the virus fails to be deposited. For example, Schlesinger and Andrewes (1937), using the Sharples centrifuge, found that after *spinning Shope's fibroma virus for 75 minutes at 33,000 r.p.m., there was just de*tectable deposition in a medium of specific gravity 1.25. They therefore assumed that the specific gravity of the virus was 1.3, and from the results of their calculations concluded that the fibroma virus measured 126 to 141 mμ, and the papilloma virus 32 to 50 mμ. These figures closely approximated to those obtained by ultrafiltration, from which it was learned that the fibroma virus measured 125 to 175 mμ, and the papilloma agent 23 to 35 mμ in diameter.

Although the sizes of viruses and bacteria measured by Schlesinger's technique were found to be in good agreement, they invariably appeared to be about 30 per cent. higher than the values obtained by ultraviolet light and ultrafiltration, and accordingly Elford (1936) reinvestigated the problem and introduced the inverted *capillary tube technique which overcame certain disadvantages associated with* Schlesinger's (1932) technique.

Elford's (1936) improved method greatly facilitated the obtaining of samples of material after centrifugalization, and minimized the possibility of redispersal of the virus particles after their deposition. It also enabled the investigator to compare the difference in infectivity of the fluid within the cell before and after centrifugalization, from the results of which it was possible to calculate the size of the virus particles (*d*) by direct application of Stokes' law, the following formula being used:

$$d = 7.94 \times 10 \sqrt{\left(\frac{\eta \log \frac{x_1 + l}{x_1 + lC_t/C_0}}{(\sigma_p - \sigma_m) N^2 t}\right)},$$

where d = the diameter of the particle in mμ, x_1 = the distance of the top of the capillary from the center of rotation (= 7.25 cm. for metal cell or 6.75 cm. for glass cell), l = depth of inverted capillary tube (= 1 cm.), σ_p = the density of the particle, σ_m = the density *of the medium*, η = *the viscosity of the medium*, N = the speed of rotation in r.p.m., t = the time of centrifugalization in minutes, C_0

CHAPTER VII

SOME PHYSICO-CHEMICAL PROPERTIES OF MAMMALIAN VIRUSES

The Sedimentation Constant and Molecular Weight

Svedberg and Nichols (1923) demonstrated that the rate of sedimentation of gold sols in a convection free cell could be measured quantitatively in a specially con-

and Lauffer (1943).

The following are some of the many factors which enter calculations to find the sedimentation rate and molecular weight of particles. molecular weight (M), angular velocity in radians per second (ω), distance from axis of rotation (x), density of the medium (ρ), density of the particle (σ), partial specific volume of the particle (V), molar frictional sedimentation coefficient (f_s), frictional coefficient of unsolvated and spherically shaped particle (f_0), viscosity of the medium (η), sedimentation velocity per unit field of force (s), time (t), diffusion constant (D), molar frictional diffusion constant (f_D), gas constant (R), absolute temperature in degrees absolute (T), radius of spherical particle (r), concentration at any time (C_t) and at original time (C_0), radial distance to meniscus is (x_0) and to boundary

x_2 designa

The re

ous compc

derived by

tions should be dilute, the particles electrically neutral and large in comparison with those of the surrounding medium.

The net centrifugal force acting on a mole of particles at a distance x from the axis of rotation under these conditions is the difference between their centrifugal *weight and the buoyancy exerted by the displaced medium This force is exactly* opposed by a frictional force which depends only on the velocity of sedimentation and a frictional coefficient Thus

$$M(1 - V\rho)\ \omega^2 x = f_s \frac{dx}{dt}. \qquad (1)$$

For dilute solutions a relationship exists between the frictional coefficient effective in diffusion and the diffusion constant,

$$f_D = RT/D, \qquad (2)$$

It has been found experimentally that under a given set of conditions the frictional coefficient effective in sedimentation and that operating in diffusion are equal The frictional coefficients can therefore be eliminated from the above equations and the well-known Svedberg expression is obtained

$$M = \frac{RTs}{D(1 - V\rho)} \qquad (3)$$

The experimental value, f_s, of the frictional coefficient can be determined for a given particle from equation (1) Using the same values of M and V, f_0 can be calculated for the same particle from equation (4), i e, the frictional coefficient the particle would have if it were spherical and unhydrated. The ratio f_s/f_0, known as the frictional ratio, must be equal to or greater than unity.

If f_s/f_0 is equal to 1 0 for a given substance, its molecules must be of compact spherical shape and unhydrated If the ratio exceeds unity it can be said that the molecule is either hydrated or departs from spherical shape—or more probably both A good deal of further information is necessary before it is possible to say how much of the excessive frictional ratio is due to hydration and how much is due to asymmetry A number of protein molecules, however, have $f_s/f_0 < 1.13$ it seems that these molecules might be spherical, since such a frictional ratio would be obtained if a spherical molecule were hydrated to the extent of 30 per cent, an entirely plausible value Many proteins have much larger frictional ratios which cannot be explained as due to hydration alone, and these molecules probably deviate very markedly from spherical shape Further data on asymmetry and hydration of protein particles are given by measurement of stream birefringence, viscosity, and dielectric dispersion This subject is discussed at length by Cohn and Edsall (1943).

Optical Methods for Determining Sedimentation Rate of Viruses

Svedberg and Rinde (1924) demonstrated that if a beam of monochromatic filtered ultraviolet light of fixed wave length emitted from a mercury arc lamp was passed through the cell of ould absorb it, whereas the solvent to obtain a series of photographs ary at successive intervals Later, in which the position of the sedimentation boundary could be ascertained by measuring the deflection of light rays through regions of sharp variation in refractive index such as were present at a sedimenting boundary According to Pickels (1944), a good refractive index system is subject to fewer errors than an absorption system, and is more suitable for the study of mixtures where it is desired to learn the relative concentrations of individual components In contrast, greater proportional variation occurs in the absorptive coefficients of proteins in the ultraviolet region than exist in specific refractive indices of the visible band (McFarlane, 1935). The absorption method possesses certain advantages such as, for example, in the case of yellow fever virus, when present in infected monkey serum, this virus displays high differential absorption in the 320–440 mμ spectral region and cannot be demonstrated by the refractive index system (Pickels and Bauer, 1940).

The Sedimentation Boundary (Sedimentation Properties)

Studies on plant viruses have shown that in the case of bushy stunt virus, the particles are strictly homogeneous in size, shape, and density, resembling the molecules of a typical protein (Lauffer, 1942) Similar investigations on tobacco mosaic virus demonstrated that the agent was a rod-shaped structure measuring 15 × 275 mμ, that possessed the high molecular weight of 4×10^7 (Knight and Stanley, 1941) Further ultracentrifugation studies revealed that the tobacco mosaic virus could be rapidly disintegrated by 6M urea and 0 1 M phosphate buffer at pH 7, following which low molecular weight components appeared that were devoid of nucleic acid, did not show double refraction of flow, and were insoluble in dilute buffers and lacked the property of infectivity

In the field of human and animal virus diseases, ultracentrifugation studies have encountered varying degrees of success The Rous sarcoma agent was found to lack the property of double refraction or anisotrophy of flow so frequently observed in the case of pure plant virus proteins, the Rous agent possessed a sedi-

The sedimentation constant, $s = \frac{dx/dt}{\omega^2 x}$, is the rate of sedimentation in unit centrifugal field, and is a characteristic constant for a given molecular species under specified conditions. In order to compare sedimentation constants obtained in different solutions at different temperatures it has been suggested by Svedberg that they should be reduced to the same standard conditions Such a reduced sedimen- mentation the materials would have if dissolved

ally given in Svedberg units, i e., in units of centimeters per sec. per unit field of force multiplied by 10^{-13}. The sedimentation of hemoglobin, for example, can be expressed in the following equivalent ways

$$\begin{aligned} s_{20} &= 4\,4 \times 10^{-13} \text{ cm/sec/dyne/gm} \\ &= 4\,4 \times 10^{-13} \text{ cm/sec/unit field of force} \\ &= 4\,4 \times 10^{-13} \text{ sec (absolute units)} \\ &= 4\,4\,\text{S} \quad \text{(Svedberg units).} \end{aligned}$$

The Svedberg formula is derived without making any assumptions about the shape and structure of the particle. Molecular or particle weights calculated from this equation should, therefore, be equally free from assumptions The molecular weight M is seen to depend on s, D, V, ρ, quantities which can readily be measured experimentally.

The Effect of Electrical Charge, Density, Hydration, and Shape on Sedimentation Rate

The Svedberg equation is derived under the condition that the particles examined should be electrically neutral with respect to the medium Otherwise, an abnormal sedimentation rate is obtained owing to the resulting Donnan effect, the sedimentation of the heavier colloidal ion is retarded by the electrostatic influence *of the lighter ions In practice this effect is eliminated by the addition of a non-*sedimenting electrolyte, 0 2 M NaCl or KCl is usually sufficient for 1 per cent protein solution

The partial specific volume (V), or reciprocal dry density ($1/\sigma$), is usually determined by the pyknometer method, in which the volume displaced by a known weight of substance is measured The concentration of the solution used is determined by estimating *the dry weight of solute in the solution and in this measure-*ment some uncertainty enters since many of the solutes remain solvent tenaciously, making precise estimation of the dry weight difficult The partial specific volume as determined by this method, however, may not represent the effective partial specific volume of the same solute under actual conditions of sedimentation because of the possibility of hydration of the particle Such a change in the properties of the solute would be represented by an increase in the *frictional coefficient* f_s *of* equation (1) The net centrifugal force is changed but slightly since any increase in the centrifugal weight of the particle is opposed by the increased buoyancy of the medium Any change in f_s due to hydration results in a similar change in f_D and, since the frictional coefficients are eliminated from equations (1) and (2) to obtain the Svedberg expression (3), M as calculated from this latter equation is the weight of the particle *in the unsolvated state to a close approximation, provided* V is the value for the dried material This problem is treated mathematically by Kraemer (Svedberg, 1940), and in simple physical terms by Pickels (1942)

A compact spherical, unsolvated particle sedimenting in the ultracentrifuge will have the minimum frictional coefficient f_o given by Stokes' equation

$$(4) \qquad f_o = 6\pi\eta N \left(\frac{3MV}{4\pi N}\right)^{1/3}$$

fluenza A (PR8). Sharp, Taylor, McLean, Beard, and Beard (1944 *a*) and Sharp *et al* (1945) have shown that in solutions of sucrose, glycerol, and urea, the sedimentation rates of the influenza virus particles vary appreciably with time and consequently the density values obtained and diameters calculated therefrom may be in error. These authors have studied the sedimentation behavior of three strains of purified influenza virus in bovine albumin which possesses a high molecular weight (70,000) and a low osmotic pressure in the desired density range, and have calculated the densities of the wet virus particles. Their results are shown in Table 3.

TABLE 3

SOME PHYSICAL CONSTANTS OF THREE STRAINS OF INFLUENZA VIRUS

(from Sharp *et al*, 1945)

	A (PR8)	*B (Lee)*	*Swine*
[illegible]	742	840	727
[illegible]	1 104	1,104	1 100
[illegible]	116	124	117
[illegible]	0 822	0 863	0 850
[illegible]	52	34 5	43 3

From the value for the dry density (1/V) and that for wet density, the percentage by volume of water associated with each of the three viruses (hydration) was calculated and is shown in Table 3 Assuming that the virus particles were nearly spherical, a supposition supported by electron micrographs, the diameters were calculated from the wet densities and the sedimentation constants, using a modified form of Stokes' law

$$r^2 = \frac{9\eta s}{2(\sigma - \rho)}.$$

Similar calculations are frequently carried out in virus work, but in general the density used is that of the dried particle since the wet density is seldom known In such a case the calculated diameter is that of the dried particle.

The possibility that some viruses might exist as highly organized cells possessing external envelopes has been considered by Smadel, Pickels, and Shedlovsky (1938) and by Sharp *et al* (1944 *a*, *b*, 1945) Influenza virus particles (PR8 strain) in sucrose solutions rapidly increase in density which is followed after a period by a decrease in density. Such changes were not found in albumin solutions which have a low osmotic pressure despite their high density. According to Sharp *et al.* (1944 *a*, *b*, 1945), if a membrane-like structure surrounding the particles is postulated which permits sucrose to enter but not albumin, the particles would increase in density if placed in a sucrose solution because of loss of water through the membrane. Sucrose would at the same time enter through the membrane, and after an initial period of water loss would reach a sufficient concentration to reverse the flow of water and cause a decrease in density

Opinions contrary to these were expressed earlier by McFarlane, Macfarlane, Amies, and Eagles (1939) who investigated the subject and concluded that the weight of evidence opposed the conception that the virus particle was limited by a semipermeable membrane, and it was more in keeping with the properties of the

vaccinia had no superficial membrane According to Mudd (1944), certain animal viruses and phages showed simple cellular structure, whereas plant viruses appeared to be nucleoproteins devoid of cellular organization Electron microscope studies

mentation constant of $s = 550 \times 10^{-13}$ cm/sec/dyne/gm (550S) with a particle weight of 139×10^{6} (Stern and Duran-Reynals, 1939) Molecular weights of much lower order can also be estimated by centrifugalization (e.g enzymes), and Rothen (1940) was able to estimate the sedimentation velocity of ribonuclease with a molecular weight of 14,000. Lauffer and Stanley (1940) contend that the values elicited by application of the centrifugalization technique are remarkably constant and can readily be repeated at independent laboratories. Beard (1945) states that a population of particles possessing uniform size, density, and shape sediment at a constant rate, and so display evidence of their physical homogeniety in a tissue suspension by the formation of a sharp and smooth boundary descending in the cell during the progress of centrifugalization.

The best effects were observed with rabbit papilloma virus, preparations of which showed sharpness of sedimentation boundary comparable with that of molecular proteins and crystalline plant viruses, indicative of a high state of purity and uniformity of particle size, nevertheless, sedimentation velocity determinations by Neurath *et al.* (1941) on twelve different preparations of highly purified papilloma virus gave results which varied between s = 266 1–287.6 S with an average value of 278 S. *Corrected to 20° C. the average sedimentation constant was* $s_{20} = 280$ S This variation is well outside the error of the method, and it was suggested by Sharp, Taylor, and Beard, (1946) that the variation from one preparation to another might be accounted for on the basis of dissymmetry of shape, or more probably of the amount of water associated with the virus particle.

Equine encephalomyelitis virus produced a less sharp boundary than papilloma virus owing to interference from normal chick embryo tissue component according to Taylor, Sharp, Beard, and Beard (1943), and Sharp, Taylor, Beard, and Beard (1943)

Intensive research by numerous workers has shown that human influenza viruses A and B and the swine virus possess different sedimentation rates, but all show diffuse boundaries indicative of variation in particle size. The behavior of virus concentrated by centrifugalization is identical with that obtained by red cell adsorption and calcium phospate precipitation (Stanley, 1945). Efforts to enhance sharpness of sedimentation boundary by repeated differential centrifugalization were unsuccessful (Sharp, Taylor, McLean, Beard, and Beard, 1944 *a, b,* Lauffer and Stanley, 1944). *Diffuse boundaries suggestive of impurity were also observed in the case of* vaccinia virus (McFarlane *et al*, 1939, Smadel *et al.*, 1940, Beard, Finkelstein, and Wyckoff, 1938). There was evidence to show that in the case of bacteriophage the sedimentation characteristics of a *B. coli* phage named T_2, designated γ by Delbruck and Luria (1942), could be changed by alterations in hydrogen ion concentration. Sharp *et al* (1946) discovered that two sedimentation constants could be demonstrated under different conditions of pH Below pH 5.8 the value for the single sharp boundary was s = about $1{,}000 \times 10^{-13}$ and above this level $s = 700 \times 10^{-13}$ At pH 5 8, both boundaries were seen together No explanation for these findings was apparent although experiments with lucite models sedimenting in salt solutions suggested that the two sedimentation boundaries of bacteriophage might be due to different states of dispersion of the particles, the sharp boundary with $s = 1{,}000 \times 10^{-13}$ might represent the phage particles dispersed as units Yellow fever virus particles likewise sedimented with a blurred boundary estimated at $18\text{–}30 \times 10^{-13}$ according to Pickels and Bauer (1940)

Density Measurements

By altering the density of the fluid in which virus bodies are dispersed, it is possible to change the sedimentation velocity of a virus in the centrifugal field, and hence to determine the density of the particles Thus sucrose, glycerol, and urea have been employed for the study of vaccinia by Smadel, Pickels, and Shedlovsky (1938), and sucrose was used by Lauffer and Stanley (1944) in their study of In-

fluenza A (PR8). Sharp, Taylor, McLean, Beard, and Beard (1944*a*) and Sharp *et al.* (1945) have shown that in solutions of sucrose, glycerol, and urea, the sedimentation rates of the influenza virus particles vary appreciably with time and consequently the density values obtained and diameters calculated therefrom may be in error. These authors have studied the sedimentation behavior of three strains of purified influenza virus in bovine albumin which possesses a high molecular weight (70,000) and a low osmotic pressure in the desired density range, and have calculated the densities of the wet virus particles. Their results are shown in Table 3.

TABLE 3

SOME PHYSICAL CONSTANTS OF THREE STRAINS OF INFLUENZA VIRUS

(from Sharp *et al*, 1945)

Opinions contrary to these were expressed earlier by McFarlane, Macfarlane, Amies, and Eagles (1939) who investigated the subject and concluded that the weight of evidence opposed the conception that the virus particle was limited by a semipermeable membrane, and it was more in keeping with the properties of the particle to postulate a rigid or semirigid structure akin to a giant protein molecule. Elementary bodies were unaffected by drying, extraction with ether or benzene, and could be redispersed in aqueous medium without detectable loss of infectivity Few animal cell semipermeable membranes would be capable of withstanding the drastic [illegible] that the elementary bodies of vacci[illegible] o Mudd (1944), certain animal virus[illegible] whereas plant viruses appeared to be[illegible] organization Electron microscope studies

on vaccinia virus after peptic digestion have suggested that it contains an outer envelope with a central dense area resembling a nucleus (Dawson and McFarlane, 1948).

Behavior of Elementary Bodies in the Tiselius Electrophoresis Apparatus

Electrically charged particles of colloids and proteins in an electric field behave in a manner similar to that of ions in an electrolyte. Among a mixture of components, particles possessing similar electrical properties migrate at a characteristically uniform rate either to cathode or anode, depending on the particle charge (Tiselius, 1930, 32, 37; Theorell, 1934; Longsworth, 1939). The quantitative electrophoretic analysis of colloids is carried out in a specially designed U-shaped tube of rectangular cross section in which a sharp boundary can be formed between the protein solution and the pure solvent. The migration of this boundary under the influence of an applied electric field is followed by optical methods similar to those used in determining the sedimentation velocity in the ultracentrifuge

Papilloma virus, in a concentration of 2 7 to 4.5 mg per ml, moves in a single sharp boundary in the pH regions 3.78 to 4.1 and 6 54 to 7.7, agglomeration and precipitation occurring about the iso-electric point at pH 5.0 (Sharp, Hebb, Taylor, and Beard, 1942). The infective properties of the virus are stable between the pH limits 3 78 to 7.7. Similar evidence of electrophoretic homogeneity is exhibited by many crystalline proteins and the hemocyanins (Sharp, Cooper, *et al.*, 1942, Abramson, Moyer, and Gorin, 1942, Shedlovsky and Smadel, 1940).

Bourdillon (1940) found the mobility of influenza A virus to be $5\ 5 \times 10^{-5}$ cm^2 $volt^{-1}$. sec^{-1} between pH 7 to 9 (ionic strength = 0 1) and 8×10^{-5} cm^2 $volt^{-1}$ sec^{-1} at pH 10 (ionic strength 0 04) The rate of migration appeared to be about the same as that of the complement fixing antigen These measurements were not made by an optical method but by estimating the infectivity at different depths in the electrophoresis cell after a given period of electrophoresis. Later more accurate work by Miller, Lauffer, and Stanley (1944) showed that influenza A (PR8) virus purified by fractional centrifugation migrated with a single sharp boundary in the pH regions 2.8–3 0 and 8 8–9 3 The iso-electric point at pH 5.3 was determined by the micro-electrophoresis method of Abramson Similar studies on vaccinia virus have been unsatisfactory according to Beard (1945), the iso-electric point has been stated to lie between pH 4 3 and 4 67 (Beard, Finkelstein and Wyckoff, 1938).

Biochemical Structure of Viruses

The introduction of the electron microscope, the analytical ultracentrifuge and

The chemical composition of several of these purified agents has been investigated, among them vaccinia (Hoagland, 1943), rabbit papilloma (Taylor, Beard, Sharp, and Beard, 1942, Beard, Bryan, and Wyckoff, 1939), equine encephalomyelitis (Taylor, Sharp, Beard, and Beard, 1943), human influenza virus A, B and swine influenza virus (Taylor, 1944).

Results of these analyses are shown in Table 4 and for the sake of comparison analyses are shown for tobacco mosaic virus (Stanley and Loring, 1938) and a normal chick embryo component of high particle weight (Taylor, Sharp, Beard, and Beard, 1942)

The tobacco mosaic virus appears to be composed essentially of protein combined with nucleic acid of the ribose or yeast nucleic type with traces of carbohydrate (Stanley and Loring, 1938) Rabbit papilloma virus appears to be one of the simplest of animal viruses resembling that of plant viruses, and consists of nucleoprotein complex of the desoxypentose type, according to Beard, Bryan, and Wyckoff (1939) The remainder of the animal viruses studied have been found to

† Ribopentose nucleic acid

be more complex and to contain an extra lipid component. Investigations into the composition of vaccinia have shown the nucleic acid to be that of the thymus type with carbohydrate present in amounts normally in excess of that associated with nucleic acid. Lipid in small amounts also forms an integral part of the structure of the elementary bodies of vaccinia and it is also possible that cholesterol is intimately associated with the particles.

The viruses of Eastern and Western encephalomyelitis represent agents of complex character and the variety of nucleic acid recovered from them has been identified as being of the ribose type similar to that of plant viruses. The proportion of lipid material is about 48 per cent. of the virus by weight, the virus can readily be hydrolyzed to produce nucleic acid of high purity. The relatively large quantity of lipid present was sufficient to permit estimation of the phospholipid, cholesterol and neutral fat content (Beard, 1945).

Influenza virus A, B, and the swine influenza virus were also shown to be lipo-nucleoprotein complexes, in which nucleic acid was found to be of the thymus or desoxypentose type. Of special interest was the nitrogen to phosphorous atomic ratio present in the lipid fraction, of the order of two atoms of lipid nitrogen to one of phosphorus, which suggested the existence of diaminomonophospholipid.

Chemical [illegible]
fluid media, [illegible]
found to be [illegible]
cholesterol and phospholipid were absent. Desoxypentose and ribopentose nucleic acids were both present, the former in excess of the latter. Comparative observations were made in the bacterial host cell and it was noted that in contrast to the phage, the lipid contained nitrogen and phosphorus and the atomic ratio of the elements indicated a phospholipid of lecithin type. Another feature of difference was the excess of ribopentose nucleic acid over desoxypentose nucleic acid in the bacterial cell.

Purification of Viruses *

Although recent work has shown that several viruses are composed of nucleoprotein, Pirie (1946) points out that nucleoprotein is a normal constituent of macromolecules, and it is not possible to differentiate viruses from normal tissue components by chemical methods. It is equally unwise to presume that all plant viruses are nucleoproteins (Darlington, 1944).

Since the chemical purification of tobacco mosaic virus was accomplished by

* This subject has recently been exhaustively reviewed by Beard (1948).

Stanley (1935–6), and work on similar lines was performed on the cucumber and tomato bushy stunt infections by Bawden and Pirie (1937), a spate of work has ensued on the chemical structure of plant viruses With the aid of the air-driven analytical ultracentrifuge it was possible to separate the infective agent from the sap of infected plants. Chemical studies revealed that the virus of tomato bushy stunt could be isolated in a true crystalline form, and those of tobacco mosaic and cucumber disease in the shape of paracrystals, moreover, they were found to consist of nucleic acid and protein exhibiting the physical behavior of homogeneous macromolecular nucleoproteins (see Wyckoff, Biscoe, and Stanley, 1937; Erikson, Quensel and Svedberg, 1936).

Chemical attempts to purify mammalian viruses have proved to be less successful for obvious reasons The bulk of these agents are intracellular parasites, and are so intimately associated with the complex tissues of the host cell that their separation from such surroundings becomes a formidable task, as Wyckoff (1945) and Beard (1945) have explained. The amounts of virus present in individual tissues vary considerably; for instance, in the case of the rabbit papilloma virus it is necessary to capture a large number of rabbits bearing tumors to provide enough material for extractions. The maximum capacity of the air-driven ultracentrifuge is limited to 200 c.c., but the 50,000 r.p.m. Sharples type of centrifuge may offer greater possibilities for large scale preparation. Viruses such as influenza and equine encephalomyelitis can be cultivated in the allantoic fluid and chicken embryo, and a large bulk of infected material can be gathered. Unfortunately, all living tissues contain much particulate matter, designated normal component, of approximately 25 mμ in size, and thus the separation of equine encephalomyelitis virus particles measuring 40 mμ cannot be accomplished by centrifugalization alone. Prolonged exposure to concentrated electrolytes results in disintegration of the normal component and thereby aids greatly the purification (Taylor, Sharp, Beard, and Beard, 1943). For similar reasons efforts to free the Rous sarcoma virus from chicken tissue component, and poliomyelitis virus from spinal cord have proved troublesome (Claude, 1938, Loring and Schwerdt, 1942).

Owing to the larger particle size of the viruses of vaccinia, influenza, and rabbit papilloma, better results have been obtained Beard (1945) mentions that technical methods other than ultracentrifugation may well be exploited with profit in the purification of viruses There are indications that the relative stability of individual viruses can be affected by variation of pH, temperature, light, salts, and salt concentration Plant viruses can be obtained in an uniform state of dispersion in either dilute buffer solution or water. Vaccinia elementary bodies, according to McFarlane (1940), clump and deposit in normal Ringer and 0 86 per cent. saline solution, but other animal viruses require a minimum concentration of 0 005 M phosphate buffer solution to maintain their respective elementary bodies in uniform dispersal.

Equine encephalomyelitis virus is readily inactivated in normal saline within 24 hours, but is stable for 21 days in Ringer fluid or 0.1 M phosphate buffer (Taylor *et al*, 1944, and Knight, 1944) There are data which also suggest that repeated centrifugation and compression of elementary bodies causes progressive loss of infectivity and irregularity of sedimentation boundary characters (Taylor, Sharp, Beard, and Beard, 1943, Taylor *et al*, 1944)

Partial purification of influenza virus strains PR8, Weiss and Lee, has been accomplished by using ethyl and methyl alcohol under accurately controlled conditions of alcohol-concentration, temperature and pH by Cox, van der Scheer, Aiston and Bohnel (1947). The latter reported that concentration was possible

fected human tissues.

CHAPTER VIII

SOME STATISTICAL METHODS IN VIRUS STUDIES

Estimation of the LD_{50} (Reed and Muench, 1938)

In experiments to ascertain the correlation between the number of elementary bodies and number of infectious units of vaccinia, Parker and Rivers (1936) applied the 50 per cent. end point method described by Reed (1936) and Reed and Muench (1938), developed from the earlier studies of Gaddum (1933) on biological standardization (Wilson and Worcester, 1943) The method of Reed and Muench has since been accorded universal recognition Because of its importance to virus workers we have reproduced the following from their original account, for the convenience of readers in field laboratories with some modifications

In the titration of sera and viruses, the end point is usually taken as that dilution at which a certain proportion of animals react or die Gaddum (1933) drew attention to the advantages of using the dilution at which 50 per cent. of the animals tested are affected, since such an end point is less affected by chance variation than any other, and is infinitely superior to the 100 per cent. end point so frequently employed The ideal method of determining this figure would be to use the largest possible number of animals at dilutions near the value of the 50 per cent reaction, and to interpolate the correct value by the procedures described by Gaddum. Unfortunately, owing to the wide limits and range of titer of biological material, too many animals are required for Gaddum's method. Reed (1936) has conceived an alternative whereby the necessity for using large numbers of animals can be obviated Two critical dilutions between which the end point should lie, are selected and the effect is that of using, at the two critical dilutions, larger groups of animals than are actually included at these dilutions. By inclining to equalize chance variations, the method tends to define the point more nearly than is possible if it is simply interpolated between the two bracketing results Reed and Muench give as an example the following hypothetical result after titration of a protective (neutralizing) serum

TABLE 5

Titration of a Hypothetical Serum
From Reed and Muench (1938)

Dilution	Alive	Dead	Total Alive	Total Dead	Percentage Mortality
a	*b*	*c*	*d*	*e*	*f*
1:1	6	0	32	0	0
1:2	6	0	26	0	0
1:4	5	1	20	1	5
1:8	6	0	15	1	6
1:16	4	2	9	3	25
1:32	2	4	5	7	58
1:64	2	4	3	11	79
1:128	0	6	1	17	94
1:256	1	5	1	22	96

Six mice are used for each dilution, and the number alive and dead entered in columns *b* and *c* The assumption is made that mice alive at one dilution would have survived at a lower serum dilution. Thus column *b* is added from below and the subtotal (i e, 32) entered in column *d* as representing the total number of mice

surviving at this plus higher dilutions. Conversely, it is accepted that mice dead at a given dilution would have died at any higher one, and so column *c* is added from above and the resulting subtotal of 22 entered at the foot of column *e* under dilution 1·256 Column *e*, therefore, represents the number of mice dying at each specified dilution plus lower dilutions The same procedure is followed throughout. From the data obtained in columns *d* and *e*, the percentage mortality is calculated and entered in column *f* Thus, for a total of 16 mice treated which received a 1.8 dilution of serum, 15 survived at that or higher dilutions and one died at 1.8 dilution and lower, the [illegible] Table 5, a graph Fig. 21 [illegible] rvivals The point of inter [illegible] point, and this lies at a serum dilution of approximately 1:30.

The authors of this method point out that the position of the end point would

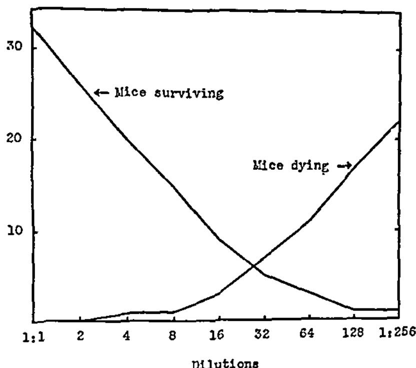

FIG. 21 Graph showing accumulation of deaths and survivals Compare with columns "d" and "e" in Table 5 on page 65 (Reed and Muench)

(Reproduced from *Amer J Hyg*, 1938, 27, 493)

be unaffected by an indefinite number of deaths at higher dilutions or survivals at lower But unfortunately, "accidental" survivals at higher dilutions and deaths at lower would alter the end-point in the direction of the predominant category It is impossible to eliminate individual animals of excessive susceptibility or enhanced resistance, but in spite of obvious limitations, the authors comment that the shift is less for the 50 per cent end point than for any other, and provided that an equal number of dilutions is taken on either side of the end point, errors resulting from accidental deaths should tend to cancel each other For this purpose, an abridged table on the lines of Table 6 is next constructed, with a 1 32 dilution of serum as its central value, because the results indicated that the 50 per cent end point was nearest to this dilution

TABLE 6

ABRIDGED TABULATION OF THE RESULTS OF TABLE 5, BASED ON THE SMALLER NUMBER OF RESULTS (from Reed and Muench, 1938)

Dilution	*Alive*	*Dead*	*Alive*	*Dead*	*Percentage Mortality*
a	*b*	*c*	*d*	*e*	*f*
1:8	6	0	14	0	0
1:16	4	2	8	2	20
1:32	2	4	4	6	60
1:64	2	4	2	10	93
1:128	0	6	0	16	100

(Note: Reed and Muench refer to dilution 1/16 as "the dilution next below," and 1/32 as "the dilution next above" in this particular example.)

The 50 per cent. end-point lies between 1:16 and 1:32, but nearer the latter. It is assumed that since the mortality at 1:32 is 40 per cent. above that at 1:16, while the 50 per cent. end-point is 30 per cent. above, the end-point is 30 per cent./40 per cent., or three-quarters of the distance from 1:16 to 1:32. The formula for the proportionate distance of the end point above the dilution, giving 50 per cent. mortality is:

$$\frac{\text{50 per cent.}-(\text{Mortality at dilution next below})}{(\text{Mortality next above})-(\text{Mortality next below})} = \text{Proportionate distance}$$

The final readings are obtained as follows:

Logarithm of 16 (lower dilution)	1.2041
0.75 (proportionate distance) × log. 2 (dilution factor)	0.2258
Sum (log. of end point)	1.4299

which makes the end point at a dilution of 1:26.9 or approximately 1:27.

The latter part of the calculations can be more rapidly completed by graphic interpolation of the final titer from a sheet of graph paper constructed according to the directions given by Reed and Muench.

This method can be applied to the estimation of the virus-neutralizing properties of any antiviral serum. Should the method be applied to ascertain the infective titer of a virus suspension (instead of, as above, the protective properties of an immune serum), the only alteration required is that the appropriate columns dealing with "deaths" and "survivals" should be reversed in direction. Table 7 shows the result of titrating a hypothetical virus.

TABLE 7

TITRATION OF A HYPOTHETICAL VIRUS

Virus Dilution	*Log. dose*	*Alive*	*Dead*	*Totals Alive*	*Totals Dead*	*Mortality Per cent.*
$\frac{1}{10,000}$	−4.00	0	6	0	16	100
$\frac{1}{32,000}$	−4.50	1	5	1	10	91
$\frac{1}{100,000}$	−5.00	3	3	4	5	55
$\frac{1}{320,000}$	−5.50	4	2	8	2	20
$\frac{1}{1,000,000}$	−6.00	6	0	14	0	0

Calculation of Results.

The 50 per cent. lies between 1/320,000 and 1/100,000 and nearer the latter. The formula for the calculation of the proportionate distance is

$$\frac{\text{50 Per cent} - (\text{Mortality at dilution next below})}{(\text{Mortality at dilution next above}) - (\text{Mortality next below})} = \frac{50 - 55}{20 - 55} = \frac{-5}{-35} = \frac{1}{7} = 0.143$$

Logarithm of the lower dilution	−5.00
Proportionate distance × log dilution factor = .143 × .5 .	.0715
Sum (log of end point)	−5.0715

$$\text{The antilog of } -5.0715 = \frac{1}{117,900}$$

In addition to estimating the infective titer of virus suspensions, this method has been used in more academic studies. Thus it has been used to estimate the degree of infectivity or LD50 of vaccinia virus, and Parker and Rivers (1936) calculated that in the case of one strain (New York Central Laboratory) an average of 42 elementary bodies sufficed to cause skin infection in the rabbit. Employing the time-response relationship method, examination of a different strain of vaccinia studied by Sprunt, Marx, and Beard (1940) showed that the ratio of infectious units to the number of bodies was an average of 1.366. The highest degree of correlation between virus mass and infectious capacity was observed in the case of rabbit papilloma virus, using the incubation period method. Bryan and Beard (1939, 1940) found that the average 50 per cent end point infectious unit or LD50 of the papilloma virus was $10^{-8.855}$ *gm, corresponding to approximately 50,000,000 particles*, indicative of low virulence to the rabbit.

The average 50 per cent. end-points of human influenza A and B virus and the swine virus cultivated in chicken embryo tissues were found to be 80, 600, and 60 *particles, respectively (Beard, 1945). In studies on Eastern equine encephalomyelitis*, Eastern type, it was revealed that 250 particles per 0.05 ml. were required to infect mice (Taylor, Sharp, Beard, and Beard, 1943)

Calculation of the Dosage-Mortality Curve from Small Numbers (Bliss 1938)

Toxicological studies on various multicellular animals show that the typical [illegible] moid type Thus a plot of the [illegible] function of the dosage along [illegible] in percentage kill per unit of the abscissa is smallest near mortalities of 0 and 100 per cent., and largest near 50 per cent.

Bliss (1938) showed that it was possible to convert the sigmoid curve to a straight line by transforming dosage to logarithms, and the percentages to a function of the normal curve, such as the "probit." Persons employing *the method* should read Bliss's paper for the requisite table for conversion of *percentage mortality* to corresponding "probits" (or probability units) for transforming the normal sigmoid dosage curve to a straight line graph—or regression line (see Fig 22 [Probit analysis and statistical treatment of the sigmoid response curve are fully described by Finney (1947)] The method was originally evolved to satisfy the requirements of pharmacologists seeking to measure the toxicity of *varying dilutions* of drugs to small groups of animals, such as for measuring the effect of gelsemicine hydrochloride on New Zealand red rabbits (Chen, Anderson, and Robbins, 1938) It was employed by Richardson and Thurber (1933) to estimate the toxicity of sodium fluoride to grasshoppers The relative merits of typhus vaccines *have also* been assayed by Bliss's method (Fulton *et al*, 1946). The theory and practice of biological assay and a review of 275 publications have been referred to by Bliss and Cattell (1943)

Crawley (1948), who has had practical experience with this method in virus studies has recommended the following procedure when setting up a test Mice do not need to be of uniform age, weight, sex, or homozygous, since the degree of such variation is apparent by the slope of the graphic regression line However, the greater the uniformity of susceptibility among the animals to a particular infection, the more accurate will be the determination of positions on the regression line. The Bliss method has been designed to allow the use of such heterozygous animals as rabbits and grasshoppers, and calculations are based on the underlying principle of the sigmoid character of the dosage-mortality response curve Further-

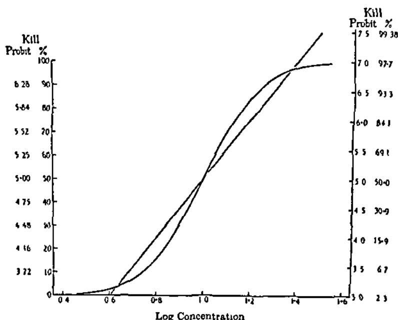

Fig. 22 Bliss's probit method, transformation of sigmoid curve (Reproduced from Finney, D J, 1947, *Probit Analysis*, Cambridge University Press)

more, allowance is made for the number of animals employed and the level of response observed

Owing to the variability of response and the relative degree of suspectibility of the species to various routes of inoculation with different viruses, it is necessary to select that particular route of inoculation which yields the most reliable results For example, when using influenza virus, mice are inoculated intranasally, with the encephalitis group of viruses, the intracerebral route is usually employed, and with the group of viruses which attack the skin the intradermal route is the method of choice.

A two, three, or four dose assay using larger groups of animals is preferable to a multiple dose assay which employs small groups The latter test does not give the maximum obtainable information because of the inevitable wastage of animals at the 0 and 100 per cent levels The doses of virus should be carefully selected so that the graded response may be expected to lie within the range of 5 to 95 per cent., and to "straddle" the 50 per cent end point In order that this range of dosage may be achieved, a carefully titrated stable stock of virus is essential

When planning a test, the number of animals which must be used depends on

the degree of accuracy desired for the material under test. The more accurate the result desired, the greater must be the number.

When performing an antigenicity test on a vaccine, two procedures are possible. Th
live
of
is
vaccine. The second provides a more accurate assessment of the immune response of the animal population to a given stimulation, and approximates more closely to circumstances pertaining to nature.

In preparation for the antigenicity test, the infective titer of the virus to be used for challenge material must be carefully measured. Furthermore, the stock preparation of infective virus must be stable, so that consistent results may be obtained over a long period of time. The LD50 of the virus preparation can be defined within quite narrow limits when the results from the preliminary tests are analyzed statistically. In the case of the stock virus (A) used in the experiments shown in Table 8, the LD50 had been previously calculated to be −6.78 ±0.08.

It is also necessary to know the dosage-response curve for mice vaccinated with the standard vaccine. Trial experiments indicated the LD50 value for mice vaccinated with a given quantity of the standard vaccine (C) was −4.20 ±0.15, and that the average slope of the regression line was 0.80 ±0.20.

Unknown vaccines may be tested by either of the following methods

1. A preliminary trial test is made using small numbers of animals at widely spaced doses, so that the greatest range of activity that might be encountered is covered. In practice this range is narrowed considerably with increasing experience. With this preliminary estimation of the position of the regression line, it is possible to select a dose which will approximate the LD50. The trial test of the *unknown vaccine (B) (Table 8) indicated that the LD50 was approximately −5.60.*

TABLE 8

TABULATED RESULTS OF A HYPOTHETICAL ANTIGENICITY EXPERIMENT IN MICE

Mice	*Log dose*	*Mortalities*	*Probits*	*Calculated LD50*
A				
Unvaccinated controls	−7.60	2/14*	3.93	
(Virus titration)	−6.78	6/15	4.75	−6.65 ± 0.18
	−6.00	12/15	5.84	
B				
Test vaccine treated	−6.80	2/15	3.89	
	−5.60	7/15	4.92	−5.64 ± 0.21
	−4.40	14/15	6.50	
C				
Standard vaccine treated	−5.40	3/15	4.16	
	−4.20	8/15	5.08	−4.34 ± 0.28
	−3.00	14/15	6.11	

* 1 nonspecific death (due to trauma)

2. If numbers of animals and expense are of no concern, then the unknown vaccine may be tested as follows. A sufficient number of groups of mice is vaccinated with the unknown vaccine, so that the entire range of activity of the virus preparation may be covered using evenly spaced doses. In this way the position of the regression line of the unknown vaccine may be obtained with sufficient accuracy so that comparisons can be made with the standard vaccine.

The average slope of the regression lines has been determined by the results of previous experiments. In general, it will be found that vaccinated mice do not respond as uniformly to the inoculation of living virus as do the unvaccinated con-

trols. By the use of the expected slope of the regression lines, it is possible to choose suitable dilution factors for the dosage of virus, so that mortalities between 5 and 95 per cent. may be obtained. The expected LD50 is used as the mid point.

One hundred and thirty-five mice are dealt by random selection into 9 groups of 15 animals each The groups are then assigned to the various positions of the test at random. Three groups are assigned for the purpose of unvaccinated controls (A). Three groups are vaccinated with the test vaccine (B), and the remaining three groups are inoculated with the reference vaccine (C).

After a suitable time interval (usually 14 days) the mice are challenged with known quantities of living virus.

The results of a statistical analysis of the data presented in Table 8 and Fig. 23 show that there is a highly significant (real) difference between the position of

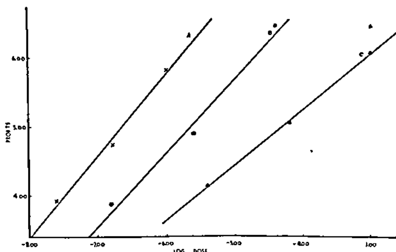

FIG. 23 Bliss's probit method for assay of vaccines, as described in the text

each of the three regression lines This is interpreted as follows The unknown vaccine (B), while giving a significant degree of protection, is not as good as the standard vaccine (C) Since the differences in the results are highly significant, there is no need of further testing of the unknown vaccine (B).

If more exact determinations are required, as in borderline cases, the accuracy of the test may be increased by using larger numbers of animals

It should be noted that the above outline is only a generalized summary of the procedure to follow in an antigenicity test. Each virus has its own particular set of variables, and ways must be devised to meet the particular situation at hand

CHAPTER IX

THE PARTICULATE NATURE OF VIRUSES—A SUMMARY OF RESULTS

As EARLY AS 1887 Buist of Edinburgh (Gordon, 1937; Mackie and van Rooyen, 1937) and later, Paschen (1906) of Hamburg, observed independently that the causal agent of vaccinia was a minute micro-organism that could be demonstrated in stained preparations under the ordinary microscope. In succeeding years other workers made similar observations in connection with other virus diseases, and at the present time it is generally accepted that the designation "ultramicroscopic and invisible viruses" is frequently a misnomer, for certain are capable of being stained and can be seen with the ordinary microscope. The limit of visibility attainable with the ordinary microscope has been fully discussed elsewhere (Chapter I), and it only remains to repeat that any virus possessing a size of 67 mμ should (according to Coles, 1929) be visible as a stained particle under the ordinary microscope Under darkground illumination the limits of resolution are greatly enhanced, and it should therefore be possible to see particles even smaller than this—a fact which has been fully supported by the observations of Merling-Eisenberg (1938), who succeeded in demonstrating phage particles measuring 25 mμ in size by the use of *darkground illumination and an optical system possessing a numerical aperture of* 1 25.

The following is a list of viruses which have been stained and demonstrated under the microscope in the form of elementary bodies canary-pox, mouse ectromelia, fowl-pox, herpes simplex, inclusion conjunctivitis, infectious myxomatosis of rabbits, Japanese encephalitis, lymphogranuloma inguinale, molluscum contagiosum, measles, psittacosis, pneumonitis, rabbit fibroma of Shope, trachoma, variola, vaccinia, varicella, and zoster. References to literature regarding the elementary bodies found in these diseases are contained in Table 9.

Although these viruses are clearly visible under the light microscope, accurate size measurements are not possible Ultrafiltration and ultracentrifugation have provided evidence that viruses range in size from psittacosis which measures at [illegible] and mouth disease measuring 8–12 mμ The latter [illegible] he molecules of egg albumen (4 mμ), oxyhema- [illegible] (5 mμ), and serum pseudoglobulin (7 mμ), ac- [illegible] lford and Ferry (1934) Since the introduction of the electron microscope, fresh interest has been aroused, and the particulate size of numerous viruses has been reinvestigated The results of the latter method are, in general, in agreement with those of ultrafiltration and ultracentrifugation The electron microscope also may provide information respecting the manner of multiplication of virus particles, and the genesis of inclusions Intensive studies on the origin of bacteriophage particles in parasitized bacterial cells, and related lines of investigation, may answer the keenly debated question whether viruses reproduce like bacteria or by a different mechanism (Hook *et al*, 1946)

CHAPTER IX

THE PARTICULATE NATURE OF VIRUSES—A SUMMARY OF RESULTS

As EARLY AS 1887 Buist of Edinburgh (*Gordon, 1937, Mackie and van Rooyen, 1937*) and later, Paschen (1906) of Hamburg, observed independently that the causal agent of vaccinia was a minute micro-organism that could be demonstrated in stained preparations under the ordinary microscope. In succeeding years other workers made similar observations in connection with other virus diseases, and at the present time it is generally accepted that the designation "ultramicroscopic and invisible viruses" is frequently a misnomer, for certain are capable of being stained and can be seen with the ordinary microscope. The limit of visibility attainable with the ordinary microscope has been fully discussed elsewhere (Chapter I), and it only remains to repeat that any virus possessing a size of 67 mμ should (according to Coles, 1929) be visible as a stained particle under the ordinary microscope Under darkground illumination the limits of resolution are greatly enhanced, and it should therefore be possible to see particles even smaller than this—a fact which has been fully supported by the observations of Merling-Eisenberg (1938), who succeeded in demonstrating phage particles measuring 25 mμ in size by the use of darkground illumination and an optical system possessing a numerical aperture of 1 25.

The following is a list of viruses which have been stained and demonstrated under the microscope in the form of elementary bodies canary-pox, mouse ectromelia, fowl-pox, herpes simplex, inclusion conjunctivitis, infectious myxomatosis of rabbits, Japanese encephalitis, lymphogranuloma inguinale, molluscum contagiosum, measles, psittacosis, pneumonitis, rabbit fibroma of Shope, trachoma, variola, vaccinia, varicella, and zoster. References to literature regarding the elementary bodies found in these diseases are contained in Table 9

Although these viruses are clearly visible under the light microscope, accurate size measurements are not possible Ultrafiltration and ultracentrifugation have provided evidence that viruses range in size from psittacosis which measures at least 230 mμ to the agent of foot and mouth disease measuring 8–12 mμ. The latter approximates in dimensions to the molecules of egg albumen (4 mμ), oxyhemaglobin (4 5 mμ), serum albumin (5 mμ), and serum pseudoglobulin (7 mμ), according to Elford (1933) and Elford and Ferry (1934) Since the introduction of the electron microscope, fresh interest has been aroused, and the particulate size of numerous viruses has been reinvestigated The results of the latter method are, in general, in agreement with those of ultrafiltration and ultracentrifugation The electron microscope also may provide information respecting the manner of multiplication of virus particles, and the genesis of inclusions Intensive studies on the origin of bacteriophage particles in parasitized bacterial cells, and related lines of investigation, may answer the keenly debated question whether viruses reproduce like bacteria or by a different mechanism (Hook *et al*, 1946)

CHAPTER X

INCLUSION BODIES

The majority of virus diseases is characterized by the occurrence of organized structures in the cytoplasm or the nucleus of infected tissue cells. These structures are known as inclusion bodies, inclusions, or virus inclusions, it is necessary to define what is meant by these terms. Histologists sometimes use the term "inclusion body" in a broad sense, to refer to any structure in the cytoplasm of a cell other than such purely normal constituents as the mitochondria, Golgi apparatus, or centrosome; thus, they might refer to globules of fat or particles of glycogen as inclusion bodies. Virus workers use the term in a restricted sense, to refer to peculiar intracellular structures generally regarded as characteristic of virus infections. These inclusions may occur in the nucleus or cytoplasm, and be eosinophilic or basophilic. The question of terminology is somewhat complicated, however, by the fact that bodies similar to those occurring in virus infections may occur intracellularly in tissues which are either healthy, or else affected by a disease of nonvirus etiology. For example, while one talks about the Negri body as the characteristic inclusion body of rabies, one also says that inclusion bodies have been found in whooping-cough and brain tumors, both probably nonvirus conditions. We find *the term "virus inclusion" a useful one, but its use does not imply that we necessarily* believe all such structures to be composed solely of virus particles.

In this chapter we intend to discuss the inclusions of human viruses, and the better known inclusions of animal viruses, inclusions have also been reported in various diseases of plants, fish, and insects (Rivers, 1928, Ludford, 1930, Smith, 1930, St John-Brooks, 1930).

Concerning literature, a number of valuable papers of a general nature has appeared in recent years, some giving illustrations (Findlay and Ludford, 1926, Rivers, 1928, Ludford, 1930, Cowdry, 1934, Ishimitsu, 1937).

Classification. Various types of classification may be used in describing these structures. For example, Lipschutz (1921) divided inclusions into three groups. the cyto-oikon or intracytoplasmic body; the karyo-oikon or intranuclear body, and the cyto-karyo-oikon, the body that occurs in both sites. This terminology, however, is scarcely used at the present it is so much easier to refer simply to intracytoplasmic or intranuclear inclusions.

Cowdry (1934) has published a valuable classification of intranuclear bodies, which are divided into Types A and B, according to morphology

THE MORPHOLOGY OF INCLUSION BODIES

Intracytoplasmic

(*a*) *Large eosinophilic inclusions* measure from about 5 μ up to 20 μ in diameter. They are usually spherical, but may be oval, elongated, or triangular. These bodies commonly appear more or less homogeneous, but special methods (*vide infra*) may detect granularity. The better known virus inclusions of this type are the following the Guarnieri body of variola-vaccinia, the Negri body of rabies, the Henderson-Paterson body of molluscum contagiosum, the Bollinger body of fowl-pox, and the Marchal body of mouse ectromelia

(*b*) *Small eosinophilic inclusions* These inclusions are usually early forms of [illegible] to form a larger struc-

[illegible] ia.

[illegible] ually formed by a col-

lection, of a colony, [illegible] The typical appearance

is usually of discrete blue granules lying in a more or less circumscribed area of the cytoplasm. Small basophilic inclusions occur in encephalitis lethargica, and herpes febrilis

(*d*) *Large basophilic inclusions* Large basophilic homogeneous inclusions have been described in lymphogranuloma inguinale (Gamna-Favre bodies). Studies have shown, however, that they are probably nuclear in origin, and not true virus inclusions

(*e*) *The trachoma type of inclusion* The inclusion bodies of trachoma, inclusion conjunctivitis, psittacosis, LGI, and pneumonitis have so many features in common that they can be described together. Thus, with certain minor differences, they each undergo a series of distinctive changes while in process of development, they stain readily with Giemsa's solution, and during the early stages of growth they appear as basophilic intracytoplasmic structures As time proceeds, the inclusions not only increase in size and alter in shape, but also exhibit a tendency to acidophilic characters The mature inclusion body consists of a clump of pink-stained elementary bodies which are sometimes covered by a film of cell material stained light blue, so that the structure as a whole has a lilac tint. This appearance is most marked in the inclusion bodies of trachoma and those of inclusion blennorrhea, and is less obvious in the case of the psittacosis group of agents

During the last decade the inclusions of psittacosis have been exhaustively investigated by Bedson and Bland (see Chapter LXXI), who showed that the earliest visible growth phase of the parasite took the form of a large, apparently homogeneous, basophilic and intracytoplasmic structure which they called the plaque or plasmodium stage. As growth progressed the plaque grew in size and underwent segmentation, so that it eventually assumed the appearance of a segmented mass, called a morula Owing to the resemblance of these initial phases to the early forms of a protozoal bird parasite, Bedson expressed the view that the psittacosis virus showed morphologic similarities more related to the protozoa than to the bacteria Subsequent work by Bedson and Bland however, showed that the earliest developmental forms were in reality composed of an aggregation of smaller masses As the inclusions matured, minute pink-staining elementary bodies began to develop within them and eventually these filled the whole cell, which subsequently ruptured and discharged its contents into the surrounding tissue spaces. The free-lying virus bodies next entered healthy endothelial cells and commenced a second cycle.

The inclusion bodies of psittacosis, trachoma, and inclusion conjunctivitis constitute a unique group of structures. Owing to the facility with which they can be demonstrated in tissues and the color effects which are obtainable in film preparations, they have been examined by cytologists, certain of whom have suggested that the appearances of the inclusion body at different stages of its growth are not solely produced by the parasite itself but are also contributed to by the cell Levinthal (see Chapter LXXI), for instance, goes so far as to assert that the initial forms referred to as the plaque, plasmodium, and morula varieties represent, to a large extent, the reaction of the parasitized cell and, to a lesser degree, the virus itself. This opinion is somewhat similar to that expressed in the past by early German writers in respect of the nature of the trachoma inclusion body. They, for example, pointed out that the light blue-staining masses which developed in the cytoplasm of invaded epithelial cells after infection represented a product of cell degeneration, on account of which they called them "plastin masses" The successive developmental stages of the trachoma inclusion body have been investigated in great detail by Halberstaedter and Prowazek (see Chapter LXV), and from their survey of the literature on this subject they concluded that the first sign of growth of the virus was the formation of the initial body, inside which in turn elementary bodies, or *Strongyloplasma* as they were called at the time, began to appear This process started in the initial bodies situated at the center of the cytoplasm and gradually involved those situated peripherally, so that eventually the whole cytoplasm be-

came filled to bursting point with elementary bodies, the nucleus became pushed to one side, and the cell ruptured.

Much of what has been said regarding the morphology of the Halberstaedter-Prowazek inclusion body is equally applicable to the inclusion body of inclusion blennorrhea, and for all practical purposes they may be regarded as identical in appearance. The only outstanding difference between the two inclusions lies in their relative distribution in affected tissues, for whereas in trachoma the bodies occur only in the conjunctival epithelium, the virus of blennorrhea has also been demonstrated in the mucous membrane of the cervix uteri and, on rare occasions, of the male urethra.

An interesting observation which has been made regarding this group of inclusions is the fact that the elementary bodies appearing in the fully developed trachoma inclusion body are embedded in a jelly-like material; this substance sometimes clings to the elementary bodies after they have been liberated It is this mucoid covering which produces the halo-like zone of nonstaining material that surrounds individual elementary bodies in Giemsa-stained films (see p. 698).

The researches of Bland and Canti (see p 119), who obtained a cinephotomicrographic record of the growth phases of psittacosis virus in tissue cultures, also revealed that the inclusion body possessed a definite outer covering or envelope composed of a relatively dense substance (see p. 750). Kurotchkin *et al.*, (1947) find that treatment of yolk sac smears with ether results in the disappearance of the large forms of LGI, psittacosis pneumonitis viruses, the EB's being unaffected

The microchemical reactions of the inclusion body of trachoma have been investigated by Rice, who found that the matrix consisted of a carbohydrate substance which yielded a specific color reaction with iodine, furthermore, the inclusion could be deprived of this property by preliminary exposure to saliva. The inclusion body of inclusion conjunctivitis has also been found to react in a similar manner.

Findlay and his co-workers (1938) claim that LGI virus also undergoes a developmental process similar to that of psittacosis (see p. 774)

Intranuclear

Cowdry (1934) states that the characteristic features of these inclusions are as follows eosinophilic staining reaction, presence of an unstained halo between the inclusion and the nuclear membrane, and margination of basichromatin on the nuclear membrane Cowdry also reports that intranuclear inclusions can be divided into Types A and B

Type A inclusions are either amorphous, granular, or occur in rounded masses The nuclear material is severely disorganized, and the basichromatin collects on the nuclear membrane These inclusions contain no iron or thymonucleic acid, and micro-incineration leaves no ash. Affected tissues show bodies in all stages of development, thus, certain cells may contain fully developed inclusions, while nearby, only very small forms may occur There is usually a severe tissue reaction in the neighborhood of Type A bodies Type A inclusions are found most characteristically in herpes febrilis, yellow fever, chickenpox, zoster, and virus III infection of rabbits

Type B inclusions cause much less reaction in the nucleus than do Type A The inclusions themselves are more circumscribed, they vary in size and there may be a number in any one nucleus, there is no margination of basichromatin, and there is no marked tissue reaction in the surrounding areas Type B inclusions occur, for example, in poliomyelitis, Rift Valley fever, and Borna disease of horses

VIRUS DISEASES OF MAN IN WHICH INCLUSION BODIES OCCUR

Intracytoplasmic

Eosinophilic. Encephalitis lethargica (Dawson's bodies), Japanese encephalitis (Taniguchi's bodies); molluscum contagiosum (Henderson-Paterson bodies);

Intranuclear

Type A Herpes febrilis (Lipschütz bodies), herpes zoster (Lipschütz bodies); varicella, virus "B" infection, yellow fever. Intranuclear inclusions resembling those of herpes have been described in cases of subacute "inclusion" encephalitis occurring in children, the bodies are found in the neurones in the cortex, basal ganglia, inferior olive, and the horns of the spinal cord, they may also be found in the oligodendroglia (Brain, 1942–3, Greenfield, 1942–3, Russell, 1942–3, Baar, 1946).

Type B. Herpes febrilis (Nicolau's bodies), herpes zoster (Nicolau's bodies); poliomyelitis, Rift Valley fever.

CELL INCLUSIONS FOUND IN HUMAN TISSUES IN NONVIRUS DISEASES

Inclusions have been described in certain conditions for which no virus is held responsible. Thus intranuclear inclusions have been found in nerve cells of persons dying from different diseases (Wolf and Orton, 1932). Nuclear inclusions were found in the tubular epithelium of the kidney and in liver cells in a number of cases of lead poisoning in children (Blackman, 1936). A number of authors have described Type A intranuclear inclusions in the lungs of children dying from whooping-cough pneumonia (Rich, 1932, Kuttner and Wang, 1934, McCordock and Smith, 1934). Goodpasture *et al* (1939) described inclusions in the nuclei of epithelial cells in the respiratory tract of infants after measles or whooping-cough

Broadhurst *et al* (1939) found cytoplasmic inclusions in the respiratory system and blood cells after scarlet fever In later papers they refer to finding stippled bodies in the epithelium of the throat in persons complaining of "irritation" (Broadhurst, Maclean, and Taylor, 1943 *a*, *b*) Cytoplasmic inclusions may occur in the lymph nodes in Hodgkin's disease, and have been studied in tissue culture (Grand, 1944). Eosinophilic cytoplasmic inclusions have been described in tropical phlebitis (Fisher, Fisher, and Lendrum, 1947)

Gliomata, mainly those of the spongioblastoma multiforme type, may contain large eosinophilic intracytoplasmic inclusions (Russell, 1932, Wolf and Orton, 1933–4) Similar bodies may occur in meningioma, perineural fibroblastoma, and hemangioblastoma (Wolf and Orton, 1933–4) Bland and Russell (1938) described intranuclear inclusions in cultures of meningiomata

INTRACELLULAR INCLUSIONS FOUND IN APPARENTLY HEALTHY HUMAN TISSUES

Structures resembling virus inclusions have been found in the tissues of healthy persons on a number of occasions

Type A intranuclear inclusions were found in the intestines, liver, and lungs of a man aged 36 (VonGlahn and Pappenheimer, 1925)

Type B inclusions have been found in the kidneys in a number of healthy human beings (Cowdry *et al*, 1935), and in the male genital tract in the columnar cells of the part derived from the wolffian duct, being closely associated with spermatogenesis (Gilmour, 1937)

A number of authors has described intranuclear inclusions in healthy young children (e.g., Goodpasture and Talbot, 1921; Farber and Wolbach, 1932; Kuttner and Wang, 1934; Pappenheimer and Hawthorne, 1936, for other references see VonGlahn and Pappenheimer, 1925) The patients were usually infants; sometimes still-born fetuses were examined. The inclusions occurred in the bile ducts, intestine, kidneys, liver, lungs, pancreas, parotids, thyroid, and respiratory tract Farber and Wolbach found both [illegible]
of submaxillary glands examined
by Kuttner and Wang (1934) F
of infants are Cappell and McFarlane (1947) and Kalfayan (1947).

Acidophilic intranuclear inclusions appeared spontaneously in cultures of human fetal leptomeninges, and in fibroblast cultures from human fetal lung (Fischmann and Russell, 1940).

CELL INCLUSIONS OBSERVED IN ANIMAL VIRUS DISEASES

Intracytoplasmic

Eosinophilic. Canary-pox; dog distemper, ectromelia (Marchal bodies); foot-and-mouth disease in animals, fowl-pox (Bollinger bodies); louping-ill; myxomatosis of rabbits, ferret epizootics (Slanetz and Smetana, 1937, Spooner, 1938); fowl plague, sheep-pox, cow-pox.

Basophilic. Psittacosis, ornithosis, and pneumonitis.

Intranuclear [1]

Type A. Fox encephalitis, louping-ill, infectious tracheitis of chickens, an owl disease, parrot and parakeet disease, pseudorabies, rats infected with an active principle in sewage (Hindle and Stevenson, 1929–30, Hindle, 1932), salivary gland virus of guinea-pigs, generalized visceral disease of guinea-pigs (Pappenheimer and Slanetz, 1942), salivary gland virus of mice; salivary gland virus of rats, virus III of rabbits, virus of feline agranulocytosis (Hammon and Enders, 1939, Syverton *et al*, 1943).

Type B. Borna disease of horses, infection of the livers of mice (Findlay, 1932).

CELL INCLUSIONS OCCURRING IN HEALTHY ANIMAL TISSUES

Inclusions have been found in a number of apparently healthy animals, it should be realized, however, that viruses may be present in these conditions as it is now known that there exists a number of more or less benign virus infections of animals

Monkeys. Intranuclear inclusions have been found in the respiratory system and bile ducts (Covell, 1932), in the kidneys (Cowdry and Scott, 1935 *b*), and in the liver cells [illegible] .6)

Dogs. [illegible] demonstrated in the liver cells of 2 dogs by [illegible] inclusions were demonstrated in the liver and kidney cells of dogs over two years of age (Nicolau and Kopciowska, 1936).

Cats Normal cats may show small intracytoplasmic granules in their nerve cells (Negri-Luzzani, 1905, 1913)

Guinea-pigs Pappenheimer and Hawthorne (1936) found nuclear inclusions in the liver cells

Mice Negri-like bodies may occur in the nerve cells (Nicolau, Kopciowska, and Balmus, 1933) or liver (Campbell, 1939)

Rats Hurst *et al*, (1943) found intranuclear inclusions in the kidneys of a number of wild rats (see also Syverton and Larson, 1947)

Opossums Hurst *et al*, (1943) found intranuclear inclusions to develop in the kidneys of Australian opossums kept under hygienic laboratory conditions

[1] Many of these inclusions have been personally studied by Cowdry (1934)

Ferrets. Inclusion bodies were found in the nuclei of the liver cells by Pappenheimer and Hawthorne (1936).

Moles. Intranuclear bodies were found in the salivary glands by Rector and Rector (1934).

Birds. Type A lesions were found in the kidneys of a Guatemalan amazon, Type B lesions were found in the lungs of this species and the kidneys of a number of other birds (Cowdry *et al.*, 1935).

Frogs. Cowdry (1934) found Type A lesions in the kidneys of frogs.

Tissue cultures. Acidophilic intranuclear inclusions have been described in cultures of leptomeninges from chick and rat embroys, and in fibroblast cultures from the lungs of rat fetuses (Fischmann and Russell, 1940)

MULTIPLE INCLUSIONS

Under certain conditions, single cells may show more than one type of inclusion Thus, Syverton and Berry (1947 *a*) found that the cells of a Shope's rabbit papilloma could be injected with B virus and myxoma They also showed that the cells of the rabbit cornea might show cytoplasmic vaccinial inclusions, and nuclear inclusions of B virus or herpes (1947 *b*).

THE PRODUCTION OF INCLUSIONS BY PHYSICAL AND CHEMICAL AGENTS

A number of physical and chemical factors have been said to cause inclusions when inoculated into experimental animals.

Intracytoplasmic. 1. Russell's viper venom produced Negri-like bodies in nerve cells in guinea-pigs (Acton and Harvey, 1911).

2. *B. pyocyaneus* injections produced Negri-like bodies in rabbits (Acton and Harvey, 1911).

3. Prolonged administration of pilocarpine produced Negri-like bodies in the salivary glands (Shortt and Lahiri, 1934).

Intranuclear. 1. Inclusions were produced in guinea-pigs by injections of certain aluminium, carbon, and iron compounds, these structures gave negative Feulgen and MacCallum reactions, and so were clearly not of nuclear origin (Olitsky and Harford, 1937).

2. Bismuth injections gave rise to nuclear inclusions in rats (Pappenheimer and Maechling, 1934)

3 Lee (1933–4) produced intranuclear inclusions in the nerve cells of cats after intravenous injection of glucose, common salt, sodium bicarbonate, and distilled water After injection of salyrgan, he found inclusions in the pancreas, kidneys, testes, and suprarenals In a more detailed study (1936) he produced Type B lesions in the cells of the anterior horn by intravenous injection of distilled water Following injection of hypertonic glucose, glucose plus acacia, common salt, and sodium bicarbonate, Type A lesions developed in Purkinje cells, in anterior horn cells, in cells of the spinal and sympathetic ganglia, and in pyramidal cells

4 Nuclear inclusions were produced in the kidneys of guinea-pigs, mice, and rats by the administration of lead, these structures gave a negative Feulgen reaction (Blackman, 1936)

5 Intranuclear inclusions developed in nerve cells after prolonged electrical stimulation of nerves in turtles, cats, and monkeys (Heinbecker and O'Leary, 1930)

6 Soaking nerve tissue in hypertonic saline produced nuclear inclusions (Davenport *et al.*, 1931).

7. Administration of irradiated ergosterol produced intranuclear inclusions in the kidneys of rhesus monkeys, and in the parotid and submaxillary glands of cebus monkeys (Cowdry and Scott, 1935 *a*)

A number of authors has described intranuclear inclusions in healthy young children (e g., Goodpasture and Talbot, 1921, Farber and Wolbach, 1932, Kuttner and Wang, 1934, Pappenheimer and Hawthorne, 1936; for other references see VonGlahn and Pappenheimer, 1925). The patients were usually infants, sometimes still-born fetuses were examined. The inclusions occurred in the bile ducts, intestine, kidneys, liver, lungs, pancreas, parotids, thyroid, and respiratory tract. Farber and Wolbach found both nuclear and cytoplasmic inclusions in 12 per cent. of submaxillary glands examined in infancy. Similar intranuclear bodies were found by Kuttner and Wang (1934). Recent authors describing inclusions in the organs of infants are Cappell and McFarlane (1947) and Kalfayan (1947).

Acidophilic intranuclear inclusions appeared spontaneously in cultures of human fetal leptomeninges, and in fibroblast cultures from human fetal lung (Fischmann and Russell, 1940).

CELL INCLUSIONS OBSERVED IN ANIMAL VIRUS DISEASES

Intracytoplasmic

Eosinophilic Canary-pox; dog distemper, ectromelia (Marchal bodies), foot-and-mouth disease in animals, fowl-pox (Bollinger bodies), louping-ill, myxomatosis of rabbits; ferret epizootics (Slanetz and Smetana, 1937, Spooner, 1938); fowl *plague, sheep-pox, cow-pox.*

Basophilic. Psittacosis, ornithosis, and pneumonitis.

Intranuclear [1]

Type A. Fox encephalitis, louping-ill, infectious tracheitis of chickens, an owl disease, parrot and parakeet disease, pseudorabies, rats infected with an active principle in sewage (Hindle and Stevenson, 1929–30, Hindle, 1932), salivary gland virus of guinea-pigs, generalized visceral disease of guinea-pigs (Pappenheimer and Slanetz, 1942), salivary gland virus of mice, salivary gland virus of rats; virus III of rabbits, virus of feline agranulocytosis (Hammon and Enders, 1939, Syverton *et al*, 1943).

Type B. Borna *disease of horses, infection of the livers of mice (Findlay, 1932)*

CELL INCLUSIONS OCCURRING IN HEALTHY ANIMAL TISSUES

Inclusions have been found in a number of apparently healthy animals, it should be realized, however, that viruses may be present in these conditions as it is now known that there exists a number of more or less benign virus infections of animals

Monkeys Intranuclear inclusions have been found in the respiratory system and bile *ducts* (Covell, *1932*), *in the kidneys* (Cowdry and Scott, *1935 b*), and in the liver cells [illegible] 936)

Dogs [illegible] e demonstrated in the liver cells of 2 dogs by [illegible] inclusions were demonstrated in the liver and kidney cells of dogs over two years of age (*Nicolau* and *Kopciowska*, 1936)

Cats Normal cats may show small intracytoplasmic granules in their nerve cells (Negri-Luzzani, 1905, 1913)

Guinea-pigs Pappenheimer and Hawthorne (1936) found nuclear inclusions in the liver cells

Mice. Negri-like bodies may occur in the nerve cells (Nicolau, Kopciowska, and Balmus, 1933) or liver (Campbell, 1939)

Rats Hurst *et al*, (1943) found intranuclear inclusions in the kidneys of a number of wild rats (see also Syverton and Larson, 1947)

Opossums. Hurst *et al*, (1943) found intranuclear inclusions to develop in the kidneys of *Australian opossums* kept under hygienic laboratory conditions

[1] Many of these inclusions have been personally studied by Cowdry (1934)

It may be said that virus inclusions usually give negative Feulgen and MacCallum tests, resist solution in hydrochloric acid, do not react to tests for mitochondria, the Golgi apparatus, and the centrosome, do not give a positive oxidase test, and frequently stain vitally with cresyl blue.

2. *Electron microscopy* has been used by Boswell in conjunction with us, and it appears that excellent detail can be made out, the granular nature of the inclusions of ectromelia, for example, being shown to be due to the presence of elementary bodies (Boswell, 1947).

3 *Tissue culture and egg culture.* Viruses may be added to the cells of a tissue culture, and the development of characteristic inclusions studied in wet, or preferably stained, preparations; the slide technique of growing cells is probably the best suited to this purpose (see also Ch XII). By such means the inclusions of herpes febrilis, lymphogranuloma inguinale, psittacosis, and vaccinia have been studied.

Viruses may be inoculated in fertile eggs (see also Ch. XIII); after an appropriate period of growth, the chorio-allantois is removed, and histological preparations made By this technique, the inclusions of herpes, lymphogranuloma, psittacosis, and vaccinia have been studied Agents of the psittacosis group produce inclusions in the cells of the yolk sac after local injection Andrewes (1930) has shown that the addition of immune serum prevents the development of herpetic inclusions (Lipschütz bodies). Grafts of human skin can be placed on the chorio-allantois and infected with virus, by this means the intranuclear inclusions of zoster have been studied (Goodpasture and Anderson, 1944). Human chorion and amnion have also been grafted, and the inclusions of herpes, variola, and vaccinia studied (Goodpasture and Anderson, 1942) Fowl skin has also been grafted and the inclusions of fowl-pox studied (Goodpasture and Anderson, 1940)

4. *Animal inoculation* Inclusion bodies are, of course, frequently studied experimentally in the tissues of infected animals, a particular application of this method has been used in the study of life cycles For example, in the study of psittacosis, mice were injected with virus in the peritoneal cavity, animals were killed at short intervals thereafter, and preparations made from the spleen (Bedson and Bland, 1932, see Ch LXXI) Working with lymphogranuloma inguinale, Findlay *et al*, (1938) injected mice intracerebrally, in this case also the animals were killed at short intervals thereafter In both these studies it was possible to identify a life cycle by examination of successive specimens

5. *Micro-incineration* Of recent years, it has been found that important information can be yielded by subjecting tissue containing virus inclusions to a very high temperature, after incineration, slides are examined microscopically for the nature of the residual ash Using this method, Scott (1930) found that the intranuclear inclusions of salivary gland disease of guinea-pigs left little or no ash, whereas nucleoli were found to be rich in ash A method of distinguishing between intranuclear inclusions and nucleoli is thus available Similar appearances are presented, after incineration, by the intranuclear inclusions of yellow fever (Cowdry, 1933), herpes (Rector and Rector, 1933), and Rift Valley fever (Horning and Findlay, 1934)

Danks (1932), studying intracytoplasmic bodies by micro-incineration, found that the Bollinger body of fowl-pox contained calcium salts, and was composed of numerous smaller granules, or Borrel bodies. Covell and Danks (1932) studied the Negri body, which yielded a compact white ash composed mainly of calcium

6 *Ultracentrifugation* This method was used by Lucas and Herrmann (1935) in their study of the Lipschutz body of herpes febrilis, they used the ultracentrifuge of Beams, Weed, and Pickels (Ch VI) A rabbit's cornea was excised, and cut into small pieces, 30 to 48 hours after inoculation with virus. The tissue was centrifuged for 45 to 60 minutes at 65 to 70 lbs air-pressure, fixed, and histological preparations were made The herpetic inclusions were heavier than chromatin, and passed to the pole opposite to that where the chromatin was collected

METHODS USED IN THE STUDY OF INCLUSIONS

1. *Microscopic examination.* Inclusion bodies may be examined in wet preparations by the darkground microscope, with a view to detecting granularity, infrared microscopy has also been employed. Both these methods have shown, for example, that the Negri body of rabies is a granular structure, and not homogeneous, as it appears in stained films Himmelweit (1938) has employed a very delicate microscopical method (see p. 343); he studied *in situ* by the Heine Ultropak (Leitz) microscope the chorio-allantois of ducks' eggs infected with vaccinia (and ectromelia). He found that in infected epithelial cells there were large numbers of granules, which increased in number, and were always contained in a matrix. There is little doubt that the granules were virus elementary bodies, and that the whole accumulation represented a Guarnieri body. Another method of studying vaccinia has been adopted by Merling (1940 *a*, *b*, 1943, 1945). The rabbit cornea is scarified and inoculated with vaccinia Later, cells are detached from the cornea by shaving or scraping with a knife. Cells are then placed in physiological fluid on a slide and sealed. Observation is then carried out by darkground for prolonged periods. EB's appear to enter the cell, coalesce to form Guarnieri bodies, and these rupture with the escape of EB's. Extracellular cysts, undergoing a life cycle are also seen. The observations of Himmelweit and Merling are strongly in favor of the vaccinial inclusion being a virus "colony."

As a general rule, however, inclusions are examined microscopically only after staining. Staining methods are applied for two main reasons.[1] First, as a means of demonstrating accurately the morphology of the body in question Secondly, stains and other reagents are applied to test, as far as possible, the composition of the inclusion, these tests are as follows·

(*a*) The Feulgen technique is performed as a test for thymonucleic acid. Virus inclusions usually give a negative Feulgen reaction, whether they occur in the cytoplasm or the nucleus. Lépine and Sautter (1946) have investigated a number of nuclear and cytoplasmic inclusions Thymonucleic acid was demonstrated by a positive Feulgen reaction, in rickettsiae and the inclusions of LGI and psittacosis, as well as in Guarnieri bodies (see also p 341). No thymonucleic acid was detected in the inclusions of rabies, Borna disease, yellow fever, herpes, pseudorabies, guinea-pig pneumonia, or ectromelia The bulk of inclusions probably contained no ribonucleic acid

Ingested nuclei may sometimes resemble virus inclusions, but their true nature can be detected by this reaction, for example, the so-called Gamna-Favre bodies of lymphogranuloma inguinale give a positive reaction, showing that they are of nuclear origin

(*b*) MacCallum's test detects the presence of masked iron, a positive reaction signifying the presence of nuclear chromatin

(*c*) The application of hydrochloric acid usually dissolves nuclear chromatin, but leaves inclusions intact

(*d*) Stains for mitochondria, the Golgi apparatus, and the centrosome prevent smaller forms of inclusion body from being confused with these normal intracellular structures.

(*e*) The oxidase reaction detects the presence of granules of leukocytes, which give a blue color Sometimes a flattened leukocyte may simulate a fibroblast with eosinophilic inclusions, sometimes also histiocytic cells may ingest the granules of degenerated leukocytes In both these cases the oxidase reaction shows that the intracellular structures are not true virus inclusions, but only leukocytic granules

(*f*) Intravital staining is sometimes carried out Cresyl blue solution is applied to wet preparations of tissue containing inclusions, which take up the stain selectively, to appear distinctly blue.

[1] For the technique of staining, a textbook of histology should be consulted

myelitis and zoster, we would reserve our opinion until further and more definite reports are available.

To conclude, we would summarize our views on the specificity of inclusion bodies in the following terms Certain inclusions, both cytoplasmic and nuclear, are so constantly found in virus infections that they must be regarded as specific structures produced by the respective virus agents There are, however, certain less definite inclusions, which have not been so thoroughly studied. We would not place these in the same category as those just mentioned, and we consider that their presence may be merely fortuitous, more particularly as it is evident that bodies morphologically resembling those of virus diseases can occur in conditions where the presence of any virus is improbable. The mere finding of an inclusion in a cell does not indicate a virus infection, the inclusions must occur constantly in cases of the disease, and be associated with the infectivity of the tissue in which they occur, before the possibility of a virus infection can even be considered

THE STRUCTURE OF INCLUSIONS

Any discussion on the structure of inclusions at the present day must take note of one outstanding fact. That is, that two typical intracytoplasmic inclusions—those of ectromelia and fowl-pox—have been isolated by microdissection, and found to be infective, further, one typical intranuclear inclusion—the Lipschutz body of herpes—has also been found to be infective.

There are two main theories in regard to the composition of inclusions In the first place, it is suggested that inclusions are formed from the cells of the host; that is, the inclusions are reactionary products For example, it has been variously suggested that certain inclusions may be formed by a process of degeneration of the cytoplasm or of the nucleus, that they are formed from extruded chromatin or nucleoli, that they are formed from the Nissl substance or mitochondria, or that they are formed from hypertrophied neurofibrils It is possible that the well-known Negri body is formed from nuclear material, or else from neurofibrils, but we do not believe that many other common types of inclusion can be satisfactorily explained by this theory. In the second place, it has been suggested that inclusions are intracellular colonies of virus elementary bodies We believe that this theory explains the inclusions of ectromelia, fowl-pox, molluscum contagiosum, variola-vaccinia, psittacosis, trachoma, inclusion conjunctivitis, pneumonitis, lymphogranuloma inguinale, and herpes febrilis. It is probable that the most feasible explanation of the composition of the majority of inclusions is that elementary bodies first enter the cell, sometimes reaching the nucleus, and then proliferate to form a colony. The cell itself probably reacts and produces a covering which gives the inclusion a more or less homogeneous appearance, especially is this so in the trachoma group of inclusions This theory was really advanced many years ago by von Prowazek (1907), who held that inclusions were formed from living organisms embedded in a matrix produced by the cell He coined the term *Chlamydozoa* to express the idea of organisms being clothed by a mantle of cellular protoplasmic material Later, Lipschutz (1921) regarded nuclear inclusions as reactionary products with which were associated virus particles

The problem of the biological nature of inclusions calls for much further study, at the present, too much use has to be made of analogy More experimental data, especially such as can be yielded by micromanipulation and electron microscopy, are much required

SOME STAINS FOR INCLUSION BODIES

We do not propose to discuss this question fully, as the methods are readily available in any manual on histology, but we give details of certain methods that we have found satisfactory Some methods of staining Negri bodies are described

7. *Micromanipulation* There is one method, beyond all others, of deciding whether an inclusion is a purely degenerative structure derived from the host, or whether it is infective, and derived from the parasite; that method is to isolate an inclusion by micromanipulation and then, *if possible, inject it into a susceptible* animal, eventually reproducing the infection.

The standard work on these lines was carried out by Woodruff and Goodpasture (1929), who isolated a fowl-pox inclusion by micromanipulation; it was then washed in saline, and finally injected into an animal. The washed inclusion reproduced the disease, while the saline used to wash the body *proved noninfective.* They further showed that an inclusion contained numerous elementary bodies. Baumgartner (1935 *a*) confirmed these results, and also worked with the inclusions of ectromelia of mice. She was able to reproduce the infection with a single washed ectromelia inclusion Baumgartner (1935 *b*) has also carried out important work on the intranuclear Lipschutz body of herpes The isolated body *proved infective* for the cornea, whereas the saline in which it was washed proved negative.

van Rooyen (1938) has applied this technique in another direction, he has carried out microdissection of the inclusion of molluscum contagiosum, and has shown that the body can be removed from the epithelial cell, and that it contains numerous elementary bodies embedded in a sticky matrix

The significance of the above results is undoubted, it has been shown that two very typical intracytoplasmic inclusions, and one typical intranuclear inclusion, are infective, and must, therefore, contain the viable virus particles These results have greatly influenced modern views on the nature of inclusions, and many feel that it is only a matter of time before other well-known inclusions, e.g., those of vaccinia, rabies, and yellow fever, will be treated in the same way and found to be infective

THE SPECIFICITY OF VIRUS INCLUSIONS

With regard to intracytoplasmic inclusions, we take the position that a number are absolutely specific structures that do indicate the presence of a virus. They are so characteristic in their morphology that they cannot be confused with other structures Further, they are associated with the infectivity of the tissue in which they occur, and many develop in infected tissue cultures and eggs. Such inclusions are those of rabies, variola-vaccinia, molluscum contagiosum, lymphogranuloma inguinale (Miyagawa's bodies), psittacosis, pneumonitis, ectromelia of mice, fowl-pox, trachoma, and inclusion conjunctivitis.

There are, however, certain other types of intracytoplasmic inclusion which have not been so fully studied and may be nonspecific, being unconnected with *the causal agent It is possible, however, that further study may transfer some of* these structures into the group just mentioned above *Bodies, the specificity of* which we do not yet regard as established, are Da Fano's or Nicolau's bodies of herpes febrilis, Da Fano's or Dawson's bodies of encephalitis lethargica; Taniguchi's bodies of Japanese encephalitis, eosinophilic bodies in warts, basophilic bodies in measles

With regard to *intranuclear inclusions the position is rather different For, first,* intranuclear inclusions occur in a variety of nonvirus infections, in healthy animals and human beings, and can be produced experimentally Second, there are only two common appearances presented by intranuclear inclusions—Types A and B Many nuclear inclusions, however, are found so uniformly in the particular disease, and are so *constantly associated* with the *infectivity* of the tissue in which they occur, that they may be regarded as specific structures due to the virus in question Inclusions which we so regard are those associated with yellow fever, herpes (Lipschutz bodies), Rift Valley fever, varicella, "B" virus, and virus III With regard to the intranuclear inclusions of Nicolau in herpes, and the inclusions of polio-

in Ch. LXXVI and trachoma bodies in Ch. LXV. It should also be remembered that Giemsa's method can be used to demonstrate inclusions.

Mann's Stain

We have used this particular modification with success:

Stain. 1 per cent. methyl blue, *35 c.c.; 1 per cent. aqueous soluble eosin, 15 c.c.;* water, 100 c.c.

Method. Take the section to distilled water, and treat with iodine and thiosulphate if necessary. Apply Mann's stain, and leave for 10 minutes (when possible, leave for several hours). Wash and differentiate in tap water. Wash in alcohol, treat with xylol, and mount.

H. E. Hutchison (Glasgow) advises the substitution of methyl blue (CI 706) by soluble blue (CI 707) especially for rabies material received in formol, spirit is a preferable fixative for such material.

Laidlaw's Stain

Tissues should be fixed in acetic-corrosive sublimate fixative for the best results.

1. Take section to distilled water, and treat with iodine and thiosulphate. Stain with Weigert's iron hematoxylin for 5–10 minutes. Wash well with tap water to "blue," 3–5 minutes.
2. Treat with 0.25 per cent. acid-alcohol Blue with tap water. Wash with distilled water.
3. Stain with 1 per cent. acid fuchsin for 5 minutes. Rinse with distilled water.
4. Mordant with 1 per cent. phosphomolybdic acid, 2–5 minutes Wash with distilled water.
5. Differentiate in 1 per cent. orange G in 60–70 per cent. alcohol, alternating with water to watch progress.
6. Take to alcohol, treat with xylol, and mount in dammar.

Phloxin-tartrazine (Lendrum, 1939, 1947)

This method promises to prove very suitable for phloxinophilic cytoplasmic inclusions.

Stain by hemalum (Mayer's 1903–4 formula, see Lendrum and McFarlane, 1940) for the usual time Blue and wash. Stain with 0.5 per cent. phloxin (CI 778) in water containing 0 5 per cent. calcium chloride, for 30 minutes in a jar Rinse quickly in water, drain off, and replace by a saturated solution of tartrazine NS in cellosolve (ethylene glycol monoethyl ether) from a drop bottle, and control microscopically, this acts as a differentiator. The tartrazine is very soluble in water and is easily removed by washing When the desired degree of removal of red (phloxin) has been reached, a further brief treatment with tartrazine is followed by a rinse with 60 per cent spirit, 95 per cent. and absolute alcohols, and xylol

Lendrum found structures to vary considerably in their phloxinophilia, and those found to be strongly phloxinophilic included the polymorphous cytoplasmic inclusions of warts, Kurloff bodies of the guinea-pig, and cowpox inclusions in egg membrane. The method well merits further trial

CHAPTER XI

SEROLOGICAL TECHNIQUE IN THE STUDY OF HUMAN VIRUS DISEASES

Recent studies have shown that the immunological characteristics of the filtrable viruses are analogous to those of the visible bacteria, and many serological phe- [illegible] neutralization tests— [illegible] minor modifications of [illegible] to render such tests [illegible] lty, in fact, involves [illegible] t, while bacteria are [illegible] in presence of living cells. Therefore, for certain serological tests it may be necessary to separate the virus agents from the tissues containing them This may be done by differential centrifugalization and repeated washing of tissue extracts, so that suspensions of elementary bodies are prepared. Although relatively pure suspensions of elementary bodies are thus obtainable it is impossible to eliminate all traces of antigen derived from the parasitized cells. It is therefore necessary to include a special control in the reactions, this consists of an extract of normal tissue which has been prepared from the corresponding organ of the same species as that of the animal infected with the virus under investigation This extract is prepared exactly as is that of the infected material.

For example, if an elementary body suspension obtained from rabbit's testicle is to be agglutinated with antivaccinial serum, then the antigen control should consist of a saline extract of normal rabbit's testis, which has been subjected to the same treatment as the infected tissue.

The serum controls demand special attention, and sometimes two are required for each serum tested. For example, if an antivaccinial serum has been prepared by immunizing a rabbit with vaccinia virus cultivated on the chorio-allantoic membrane of the chick embryo, then there should be a control with one sample of serum derived from another rabbit after immunization with normal chick embryo and a second from a normal rabbit. In dealing with homologous tissue, e g., when a rabbit is actively immunized with vaccinia virus cultivated in rabbit testis, a single control consisting of normal rabbit serum suffices

Innumerable modifications of the various common serological techniques have been used by virus workers It is quite impossible for us to describe the technical details of more than a few of the more representative and orthodox methods. References to other techniques will be found in the appropriate chapters, where also *the phenomenon of hemagglutination-inhibition by immune serum will* be discussed

THE PREPARATION OF SPECIFIC IMMUNE SERA

Vaccinia

Rabbits can be immunized with comparative ease against vaccinia virus. A normal animal is inoculated subcutaneously with 0 25 c c. of a 1 1,000 dilution of vaccinia virus contained in desiccated testis. After 3 to 5 days a cutaneous reaction develops at the site of injection, and thereafter the condition may either generalize (see Douglas, Smith, and Price, 1929), or else the lesion may remain localized and subsequently retrogress, depending on the virulence of the strain of virus employed Recovered rabbits are resistant to reinfection, and their immunity may be exalted by repeated doses of virus, which may be administered either intravenously

A third horse was injected with 6 subcutaneous doses of ferret lung suspension containing Shope's strain of hog influenza virus, the dosage varying from 30 to 50 c c. over a month. After one month's rest, hyperimmunization was continued and the animal received, without signs of ill effects, the remaining injections consisting of a mixture of human and porcine strains of virus cultivated in ferrets.

Antisera are readily produced in rabbits by the inoculation of two doses at weekly intervals of, for example, 5 c c. of virus-infected allantoic fluid. Antibodies also develop quickly in ferrets or mice on recovery from infection (see Chapter LXII).

VIRUS NEUTRALIZATION TESTS

Tests for virus neutralizing antibodies have been employed for three different purposes, namely (1) to assess the potency of therapeutic antisera with a view to their standardization, (2) for detecting the presence of virus neutralizing antibodies in human or animal sera for diagnostic or epidemiological purposes, and lastly, (3) to identify viruses or to investigate their antigenic structure. The general principle on which these tests are based is the same, for in the majority of instances the serum to be tested is mixed with the virus in suitable proportions, incubated for a short time, and inoculated into a susceptible animal or an egg In some tests the amount of virus used is kept constant and different dilutions of serum are added, in others the amount of serum is kept constant and the virus diluted instead.

The criteria by which individual neutralization tests are interpreted vary greatly. In general they depend on the susceptibility of the animal used, e g, in the case of neutralization tests with Rift Valley virus, as mice are employed for neutralization tests and as this virus is highly pathogenic to them, the results are interpreted according to the number of mice which survive. Should, however, a virus which is less infective to mice be employed, then after a definite interval of time all animals which do not die must be killed and examined for evidence of lesions For example, in such tests with psittacosis, the spleen of each mouse must be stained and examined for the presence of elementary or inclusion bodies before it is possible to tell whether the serum has, or has not, neutralized the virus, and in the case of tests with influenza virus the lungs of the animals are searched for evidence of consolidation.

The mouse protection test for yellow fever immune body is conducted on a different principle, thus before the serum-virus mixture is introduced intraperitoneally, the animal is given an intracerebral dose of sterile starch solution to induce the spread of virus from the brain capillaries to the brain itself, and the presence or absence of immune body in the serum tested is indicated according to the number of mice which develop fatal encephalitis (see Ch XLIII for the technique of this and other neutralization tests in yellow fever).

With a certain number of viruses it has been possible to utilize cutaneous skin reactions for titrating the antibody content of immune serum, so that several experiments can be performed simultaneously on one animal Gordon (1925) used this method for his studies on vaccinia virus and we have used it for our experiments on rabbit myxoma and Shope's fibroma viruses (van Rooyen, 1938, van Rooyen and Rhodes, 1938) The chorio-allantoic membrane of the developing chicken embryo can also be used for neutralization tests, and Burnet (1937, *et al*, 1937) showed that after inoculating the serum-virus mixture on the membrane and counting the number of pocks produced, the neutralizing powers of the serum could be estimated Certain antibodies can be titrated by inoculation of serum-virus mixtures in the allantoic cavity (influenza, see Ch. LIX), or yolk sac (equine encephalomyelitis, see Ch XCVI)

It is now customary in these tests to take the titer of the serum as the 50 per cent end-point, the point where equal numbers of animals inoculated with serum-virus mixtures show, or do not show, the lesions characteristic of the particular

or intraperitoneally (see Gordon, 1925; Craigie and Tulloch, 1931, Craigie and Wishart, 1934 *a*; Smith, 1930).

Hyperimmune sera contain agglutinins, precipitins, complement fixing and virus neutralizing antibodies. There is no standard method for estimating accurately the potency of such sera, but about 1 c.c of an active antivaccinial serum should protect against 1,000 minimal infecting skin doses, according to Andrewes (1928).

Horses. Ledingham, Morgan, and Petrie (1931) actively immunized a horse against vaccinia virus, with the aim of studying the properties of such serum as well as providing themselves with antivaccinial serum for use in cases of post-vaccinal encephalitis or smallpox.

The animal was first immunized with formolized diphtheria toxin and tetanus toxin of which 5 doses were given. Subsequently it was injected repeatedly with glycerolated calf lymph (Government strain), and during this period it was given a routine dose of tetanus toxoid every 2 or 3 months. The dosage of virus consisted of an initial intradermal inoculation of a 1·10 dilution of lymph, which was scarified into an area of shaved skin about a foot square, situated on one side of the animal's neck. Fifty hours later, a crop of about 200 vesicles developed, then gradually subsided and healed, so that after 35 days the skin had returned to its normal condition The animal was now hyperimmunized by a further inoculation of 10 c.c. of lymph given subcutaneously. This was followed 8 weeks later by 71 c.c. intravenously, a month afterward by 40 c c intravenously, and finally with 130 c.c. given intramuscularly The total bulk of glycerolated calf lymph introduced was 282.5 c.c. administered over a period of 9 months

Sample bleedings, varying in amount from 0.75 to 2.2 litres, were made at different periods during the course of immunization, and the last quantity of blood was withdrawn about 3½ months after the final intramuscular dose.

Herpes

Guinea-pigs. Antivaccinial or antiherpetic immune serum may be prepared by injecting these animals repeatedly with large doses of live virus Bedson and Bland (1929) recommended that they be given 6 to 8 doses of 1.0 to 2.0 c.c. of a 10 per cent. suspension of virus material, administered intraperitoneally, and sera prepared thus were shown to contain complement fixing antibodies.

Psittacosis

Guinea-pigs are comparatively resistant to psittacosis virus, and Bedson (1933) has successfully immunized them against this agent. A mouse was first inoculated with virus, its spleen removed and extracted with saline to make a 10 per cent. suspension of tissue. Guinea-pigs received 2 to 3 c.c. of the 10 per cent extract administered intraperitoneally at weekly intervals, with periodic rests of 1 to 2 months, each of these animals received from 10 to 15 injections, and their sera contained both virus neutralizing and complement-fixing antibodies

Influenza

The horse has been shown to be resistant to this agent, influenza virus administered intratracheally in 4 animals yielded negative results (Laidlaw, Smith, Andrewes, and Dunkin, 1935) The animals were hyperimmunized by giving each horse 12 subcutaneous injections of about 15 c c in bulk, prepared from infected ferrets' nasal mucosae, over a period of 4 months This was followed by 6 further injections of virus contained in ferret lungs, over a space of 8 weeks, at the end of which the horse's serum was found to neutralize influenza virus.

A second horse was immunized with 50 c c doses of ferret lung emulsion for 2 months, the last 3 injections of virus consisting of a mixture of both the human and porcine strains. The animal appeared to exhibit considerable reactions to the latter inoculations

tions, one mouse cage should be used for each dilution, and sick mice promptly removed Mice are observed for 10 days with the equine viruses, unless recently isolated, when 14 days suffices, as it does for St. Louis virus. For Russian and Japanese encephalitis viruses 3 weeks are required In tests with equine viruses, deaths occurring within 24 hours are regarded as nonspecific. With the other encephalitis viruses, deaths up to 48 hours are regarded as nonspecific, deaths occurring from 3 days and later should be charted as being specific.

Where additional information is required, extraneural tests may be used, or serum may be used in varying dilutions, with 10 or 100 LD50 of virus or with varying amounts of virus

Advantage may be taken of the increased susceptibility of baby mice to the extraneural injection of virus to demonstrate antibody increases Thus Lennette and Koprowski (1946) have used the extraneural test in demonstrating the development of antibodies in man following vaccination with Western equine vaccine. Mouse brain suspension was used as antigen Undiluted sera were mixed with equal volumes of virus dilution and tubes were incubated at 37° C. for one hour. Mixtures were then inoculated in 0 03 c c. quantities subcutaneously in 3-day-old mice, and cerebrally in 28-day mice. The 50 per cent. mortality end point titer of virus in the presence of pre- and post-vaccination sera was calculated and expressed as "effective virus titer"; the difference between the logarithms of the two titers was expressed arithmetically and designated "neutralization index" representing the number of LD50 of virus neutralized. When the post-vaccination sera were tested by the cerebral route, only a slight response could be demonstrated By means of the extraneural test, however, it was possible to measure a definite response

Poliomyelitis

Kolmer and Rule (1935) recommended the following method for detecting the presence of virus neutralizing antibody in human serum The spinal cords from severely paralyzed monkeys were removed, stored in 50 per cent. glycerol in the refrigerator for a month, and a saline suspension containing about 10 m l d of virus per 0 5 c c. was prepared as follows 1 gm. of the spinal cord was washed and ground up in 20 c c of saline to make a 5 per cent suspension, centrifuged at 1,500 r p m for 3 minutes, and the supernatant fluid used for the experiment Then 0 5 c c of this material was mixed with 0 5 c c of patient's serum, placed in the water bath at 37° C for 2 hours, and 0 5 c c injected intracerebrally in a *M. rhesus* monkey. The control test was carried out by inoculating another monkey with a similar suspension of virus, to which saline had been added instead of serum

Schaeffer and Muckenfuss (1940) investigated the virus neutralization test very thoroughly and made a number of suggestions for improving the technique, using monkeys More recently, virus neutralization tests have been carried out in mice, using the Lansing strain (Armstrong, 1941), by this method enough animals can be used to give a reliable result, but it is not clear to what extent antibodies to this strain develop in man (see Ch LXXXVIII) Olitsky and Findlay (1946), using the MEF strain, mixed equal parts of neat serum and serial dilutions of virus, after holding at 37° C for 2 hours, the mixtures were inoculated cerebrally in mice A serum was regarded as positive if it neutralized 100 lethal doses

Rift Valley Fever

Neutralizing antibodies to this agent have been demonstrated in the sera of human beings recovered from an attack of the disease (Findlay, 1936)

A 10^{-1} dilution of infected mouse liver was diluted with saline to form dilutions of 10^{-2}, 10^{-3}, 10^{-4}, and 10^{-5}, to each of these was added an equal volume of immune serum, and to a similar series of dilutions normal serum was added to serve as a control The two sets of mixtures were incubated at 37° C. for 4 hours, and

virus. For the calculation, a sufficient number of animals or eggs, usually 6 per dilution must be used, and the end-point worked out by a method such as that of *Reed and Muench (see Ch. VIII).*

Tests with Neurotropic Viruses

Olitsky and Casals (1947), in an authoritative paper, discuss the general principles involved in the testing of antisera for virus neutralizing antibodies against the encephalitis-producing group of
of high and uniform susceptibil
sera may be expressed by means
by calculating the LD 50 of control and test serum-virus mixtures separately, subtracting, and expressing as the antilogarithm of the difference. Thus if the LD 50 of the control serum-virus mixture is 6 5 and of the test serum mixture 4, the difference is 2 5, and the neutralization index is 320 (the antilog of 2.5). The number obtained by this calculation can, however, show only the order of magnitude of, and not the precise amount of antibody. It is recommended that for indices of 1–50 the result is expressed to the nearest whole number, 50–100 to the nearest 10, 101–1000 to the nearest hundred, 1001–10,000 to the nearest thousand, and so forth. They allude to the observations of Morgan and of Whitman that samples of serum stored at 4° C. may partly lose their neutralizing capacity, whereas sera immediately frozen retain neutralizing potency. It appears as if a complement-like heat-labile substance is responsible for at least a proportion of the virus-neutralizing effect. In all tests where acute and convalescent phase sera are compared, it is essential that both samples are stored in the same way, preferably frozen, otherwise false results will be obtained Or, as recommended by Whitman, sera heated to 56° C. for half an hour may be used, thus testing only the heat-stable neutralizing antibody.

As regards the technique of neutralization tests, several other precautions are recommended (1) Serum should be obtained with sterile precautions, several hours after a meal. After clotting for half an hour at room temperature, the serum is separated by centrifugation. Phenyl mercuric borate, 1 50,000, can be used as preservative. Hard glass ampules should be filled one-third full, and frozen on CO_2 snow

(2) The virus antigen is obtained by pooling the brains of 10 mice ill, but not dead, from infection, the brains are ground in a blender to a 20 per cent suspension in 50 per cent. or neat normal rabbit serum heated to 56° C for half an hour The suspension is distributed in glass ampules in 1 or 2 c c amounts After sealing, the ampules are quickly frozen in CO_2 and 95 per cent alcohol, and are kept frozen with CO_2 snow From time to time, the strain of virus should be checked and compared for activity, maintenance of titer, and general reliability

(3) The test recommended by Olitsky and Casals has been employed for over 20 years, and includes various modifications When thawed, the frozen virus antigen represents a 1 in 5 dilution Dilutions of 1 50, 1 500 and so forth are prepared, using as diluent 10 per cent rabbit serum in isotonic sodium chloride. The tubes receiving virus are kept in ice From each of the dilutions that are to be tested, 0.2 c c. is to be placed in each of two tubes. To one series is added 0 2 c c of neat negative human serum (or 10 per cent normal rabbit serum), this serves as the control series In the test series, 0 2 c c of unknown serum is added instead The tubes are incubated in the 37° C water bath for 2 hours, and placed in ice water prior to cerebral injection, at least 5 mice are used for each dilution For the test serum, dilutions of virus should be employed which indicate no neutralization or neutralization of at least 1,000 LD50 Thus if the LD50 of virus is usually at 10^{-8}, the control series should be made up with virus dilutions of 10^{-5} to 10^{-9}, and test sera with 10^{-4} to 10^{-7} The highest dilutions of the test series should be injected first, and the controls last To obviate the risk of secondary contact infec-

incubating the mixture at 3 ... tor overnight. The excess ... the suspension through a c... retained the virus, or else ... absorbed sera were now tested for the presence of virus neutralizing antibodies by admixture with dilute virus filtrates of about 100 m.i.d. in potency, and the result was compared with serum which was unabsorbed, but had been subjected to similar treatment. Each serum-virus mixture was incubated at 37° C. for 2 hours, and thereafter tested for infectivity by intranasal inoculation of mice. Control tests were also incorporated in the series, and it was shown that the virus neutralizing antibodies could not be absorbed by normal lung tissue From these experiments Smith and Andrewes were able to show that absorption of a serum with a homologous strain of virus removed only its appropriate antibodies, leaving the others intact.

AGGLUTINATION OF ELEMENTARY BODIES

Vaccinia

Craigie (1932) has employed the following method for obtaining a suspension of vaccinial elementary bodies·

A piece of bronze wire gauze (100 mesh) is used for scarifying the shaved back of a rabbit, a strip of the gauze (0 7 cm. by 10 cm) is held with a pair of Kocher forceps, and the virus suspension is placed on the skin of the rabbit which is then inoculated by drawing the rough edge of the gauze over the animal's back. Three days later the rabbit is exsanguinated, killed, the skin removed, cleaned with ether, pinned out on a board, and the pulp scraped off with a scalpel into two successive 10 c.c. volumes of chilled citric acid (0 004 M) one part and phosphate buffer (of pH 7 0) one part diluted 1 50 in distilled water

The pulp suspension is not ground up but is thoroughly shaken, centrifuged at 3,500 r.p.m. for 10 minutes, and the supernatant fluid removed and set aside. The deposit is once again washed in dilute buffer solution, and the supernatant fluids obtained after first and second washings are pooled. The mixture is now placed in flat angle centrifuge test tubes of 4 mm. internal diameter, and centrifuged at 3,500 r p m for 60 minutes at an angle of 28° from the vertical The elementary bodies deposited at the end of this interval are resuspended in fresh buffer solution and subjected to two further washings. The final suspension is dispersed by thorough shaking and once more centrifuged at 3,500 r p.m for 10 minutes on the ordinary centrifuge, in order to remove coarse tissue particles The supernatant fluid containing the elementary bodies is now removed, placed in a glass-stoppered bottle, excess anesthetic ether added, and stored in the ice chest until required The ether can be removed before using by placing a small quantity of the suspension in a partial vacuum Craigie and Wishart (1934 *a*) state that the yield of Paschen bodies obtained from a rabbit in 15–20 c c of dilute buffer has, when fresh, an intradermal infective titer of 10^{-8}

The density of the elementary body suspension used as antigen is standardized to match the opacity of a kaolin suspension corresponding to tube No 2 of the McFarlane standard. The tubes are compared with each other by placing them against a dark ground illuminated from behind at an angle of 45°.

A series of serum dilutions 0 25 c c in bulk is made in 0.85 per cent sodium chloride containing 1 50 citric acid phosphate buffer of pH 7 0 The elementary body suspension (*vide supra*) is diluted to twice the standard opacity in distilled water containing 1 50 of this buffer, and 0 25 c c. added to each serum dilution The mixtures are incubated in a water-bath at 50° C. for 16 hours and the results read macroscopically By means of agglutinin absorption tests Craigie and Wishart (1935) have demonstrated th... agglutinins in antivaccinial

0.4 c.c. of each serum-virus mixture was inoculated intraperitoneally in mice. The results showed that an immune serum was able to neutralize a 1:10 or higher dilution of virus, whereas normal serum was incapable of doing so, and the animals accordingly succumbed to infection in 2 to 5 days' time.

Psittacosis-LGI-Pneumonitis

Differentiation between the closely related members of this group can be achieved by means of antisera prepared in chickens; serum-virus mixtures are inoculated in mice nasally or cerebrally, according to the agent (St John and Gordon, 1947).

THE ABSORPTION OF VIRUS-NEUTRALIZING ANTIBODIES

Vaccinia and Herpes

Smith (1930) demonstrated that rabbit's testis infected either with vaccinia or herpes virus was capable of absorbing the homologous antibody from an immune serum, whereas normal rabbit kidney failed to absorb immune body from an antivaccinial serum

The specificity of the phenomenon was demonstrated by cross absorption experiments in which vaccinial testis failed to absorb herpetic antibody, and herpetic testis failed to absorb vaccinial antibody. It was also shown that each virus selectively absorbed its homologous antibody when added to a mixture of antivaccinial and antiherpetic serum. Vaccinial testis suspension, in which the virus was destroyed by heating to 58° C or 60° C. for 1 hour, showed greatly reduced power of antibody absorption

Five to 7 gm of vaccinial testis were minced with scissors in a sterile mortar with 10 c.c. of a 1 10 dilution of immune serum, and the suspension transferred to test tubes, 5 to 7 gm of normal testis (or kidney) were likewise treated and utilized as the control, 0.5 c.c of pure anesthetic ether was added to each tube which was hermetically sealed and stored for 3 days at 37° C., in order to destroy any contaminating bacteria.

After 3 days, the tubes were opened to allow the ether to evaporate, and were centrifuged at 3,000 r p m for ½ to 1½ hours The supernatant fluids were clarified by preliminary filtration through filter paper, or paper pulp, and then passed through L_2 candles under a negative pressure of 40 cm of mercury The final filtrates thus represented *(a)* immune serum treated with testicular virus, and *(b) immune serum treated with normal control tissue*

The method of antibody titration was as follows in order to compare the antibody content of any two sera, various dilutions of virus (i e, *of a suspension of* herpes or vaccinia virus contained in testis) were added to equal quantities of each of the sera, 0.2 c c of the mixtures was then injected intradermally in the shaved skin of a rabbit, using one half of the animal's back for each set of dilutions

Reactions were read on the third, fourth, and fifth days after inoculation By measuring the size of the reaction produced by each dilution, and the titer to which this occurred, it was possible to compare the virus neutralizing properties

Influenza

Absorption tests *were utilized by Smith and Andrewes (1938) for their investigations* into the complex antigenic structure of influenza virus, and they showed that each strain of virus only absorbed from a homologous serum those antibodies which corresponded to the antigenic components of the absorbing strain. Technical details regarding the method of performing the test were as follows A dilution of serum capable of neutralizing 100 m i d of virus was added to a 5 per cent. suspension of fresh infected mouse lung, and absorption *allowed to take place by*

clean glass slide with a drop of serum. The slide was then slowly tilted to and fro over an electric light bulb. With positive sera, visible aggregates could be seen by the naked eye within 2–3 minutes, negative tests remained uniformly dense.

Nineteen sera, from pigeons suffering from latent ornithosis, positive by complement fixation, were also positive by the agglutination technique.

PRECIPITIN REACTIONS

Variola-Vaccinia [1]

The following products of vaccinia virus have been proved to be precipitable with antivaccinial serum· A precipitable substance in Seitz (EK) filtrates of vaccinal pulp divisible into two antigenic fractions consisting of a thermolabile (L) portion which is destroyed by heating at 56° C for 1 hour, and a thermostable (S) component which resists 95° C. for a similar period.

Both these antigens occur in the elementary bodies of vaccinia, and participate in the agglutination of these bodies with vaccinial antiserum (Craigie, 1932, Craigie and Wishart, 1936 *a*). The LS fraction is prepared as follows.

A Seitz (EK) filtrate is dialyzed in cellophane bags A 1/10 volume of Sorensen's hydrochloric acid-citrate buffer (Clark, 1928) of pH 4 45 is added to the dialyzed filtrate and the mixture centrifuged for 30 minutes. The deposit is drained and the fluid adhering to the walls of the tube dried with filter paper. The deposit is then suspended in Sorensen's citrate caustic soda buffer of pH 6 65, the volume used being 1/10 of the final volume desired. Distilled water is added to the amount of four times this volume, the tubes shaken, centrifuged, and the supernatant fluid set aside The deposit is extracted a second time with the same volume of buffer (pH 6 65) and distilled water as previously used. The two supernatants are pooled, extracted with ether, kept for 24 to 48 hours in the ice chest, recentrifuged to deposit large particles, the supernatant fluid removed and used as LS fraction.

The antigenic properties of the L and the S components have been demonstrated by immunizing rabbits with each of them. The sera thus obtained react specifically to produce a precipitate with the homologous fraction in each instance It has been pointed out that, whereas 56° C annuls the *in vitro* activity of the L componen [illegible] it must be heated [illegible] ent, on the other [illegible] 1936)

A third precipitable substance has been obtained by extraction of elementary bodies after they have been freed from other tissue products by repeated washing. This has been termed "dissociated antigen" since it is liberated from elementary bodies *in vitro* It also consists of thermolabile and thermostable soluble precipitable substances, both of which are similar to the soluble precipitable substances found in suspensions of fresh vaccine pulp (Craigie and Wishart, 1936 *b*)

Parker and Rivers (1935, 1936, 1937) have confirmed Craigie and Wishart's findings They succeeded in extracting a chemically stable, serologically active substance from dermal and testicular tissue infected with vaccinia by boiling it with 50 per cent ammonium sulphate, followed by dialysis against running water, precipitation with alcohol, and treatment with buffered solutions About 15 mg of a white substance were derived from about 200 c c of an extract of dermal vaccine virus, and this was susceptible to digestion with commercial trypsin or pepsin but resistant to crystalline trypsin and chymotrypsin, and possessed the characters of an alcohol-soluble protein which was not precipitated by boiling in a neutral aqueous solution. A dilution of 1 640,000 gave a precipitate with an antivaccinial S antigen serum (Craigie and Wishart, 1934 *a*), but produced no reaction in a serum from which the S agglutinin had previously been removed by absorption

[1] See also p 370

sera. The two corresponding agglutinogens differ in their relative stability to heat and other agents (see Ch. XXXIII).

Zoster and Varicella

Amies (1934) has demonstrated the relationship of these two viruses to one another by means of cross agglutination reactions

Vesicle fluid was collected from patients, not more than 60 hours after the beginning of vesiculation, with a sterile capillary pipette. It was diluted in physiological saline containing 2 per cent. sodium citrate, centrifuged at low speed to deposit tissue cells, then the supernatant fluid was removed and recentrifuged at 12,000 r.p.m. for 30 minutes

The deposit (which was frequently invisible to the naked eye) was resuspended in saline of pH 7.0 containing 0.25 per cent. formalin. After a final fractional centrifugation at low speed to throw down gross particles, the supernatant fluid was removed and the suspension standardized to approximate in density that of an arbitrarily chosen elementary body suspension.

The hanging drop method was used. Dilutions of convalescent serum derived from cases of zoster and varicella were prepared from 1.4 to 1 128 in saline, mixed with an equal volume of antigen, and placed on a coverslip which was inverted over a glass slide fitted with a metal ring. The mixtures were left at room temperature (average 65° F.) for 24 to 48 hours and then examined under the microscope, using a 2/3 in. objective and × 10 ocular for evidence of agglutination A positive test was signified by the presence of highly refractile, irregularly shaped clumps

Psittacosis

Bedson (1932) has demonstrated that the elementary bodies found in this disease can be agglutinated l infected mouse spleen by fractional deposited after the final washing by ɔo r.p m

The antiserum employed consisted of the sera of guinea-pigs which had been immunized with psittacosis virus obtained from infected guinea-pig tissues Two control sera were also used, the one consisting of the serum of a guinea-pig which had been inoculated with mouse spleen tissue, and the other antiherpetic serum also of guinea-pig origin. The hanging drop technique was used for the tests and the results were read after incubating the mixtures at 37° C. for 24 hours From these experiments, Bedson proved that a suspension of psittacosis elementary bodies could only be agglutinated by homologous antiserum, and not by herpetic antiserum nor by antiserum to normal mouse spleen.

Labzoffsky (1946) has introduced a test for the laboratory diagnosis of ornithosis, using EB's grown in the egg To obtain allantoic fluid rich in elementary bodies, it was necessary to use eggs in one of the first five serial passages after transfer from the mouse Allantoic fluid was harvested from embryos dying on the fourth day or later. Fluids containing numerous elementary bodies might titer 10^8 or 10^9 on intracerebral inoculation of mice

For the preparation of the antigen for rapid agglutination tests, strongly positive allantoic fluids were pooled and inactivated with 0.4 per cent formalin After 4 days at 4° C., the material was centrifuged to throw down the elementary bodies The sediment was resuspended to 1/100 of its original volume with 0.1M phosphate buffer pH 7.2, further diluted 1/5 with normal saline, and thoroughly redispersed After "settling" overnight at 4° C., the dense supernatant constituted the antigen for the rapid agglutination test

Complement fixing antigen was prepared by inactivation of strongly positive allantoic fluid for 20 minutes at 70° C., and was used undiluted and without further treatment, material so treated contained no living virus

The rapid agglutination test was performed by mixing a drop of antigen on a

increasing quantities of complement, ranging from 1 to 10 m h d Others have diluted the antigen and kept the remaining reagents constant in volume (Craigie and Wishart, 1936).

The sequence in which the reagents are added conforms to standard serological practice, antigen, serum, and complement being added in that order. These are incubated together for either 1 hour at 37° C, as advised by Ciuca (1929) and Laidlaw and Dunkin (1931), or else for 18 to 20 hours at 8° to 10° C., as advocated by Bedson (1928), Bedson and Bland (1929), and Craigie and Wishart (1936). Others, such as Hoyle and Fairbrother (1937), in their tests with influenza virus, incubate the mixtures for 4 hours at 37° C, followed by a further period of 24 hours at 0° C, as these workers have pointed out that since the fixation of complement by mixtures of antigen and antibody may be slow, prolonged interaction is necessary. Owing to the fact that complement deteriorates rapidly if maintained at 37° C. for longer than 2 to 3 hours, when fixation is performed over a period of 16 to 18 hours' duration, low temperature is obligatory (see also Thomson, Hazen, and Buchbinder, 1932). Thus, in a review of the literature dealing with this subject, Parker and Muckenfuss (1933) have suggested that the failure of the earlier investigators to demonstrate specific complement fixation with variola-vaccinia virus, can be attributed to the fact that the virus and serum were incubated for too short a time

Antigens Used in Complement Fixation Tests

1. Tissues and exudates can be employed as a source of complement fixing antigen. Thus, the vesicle fluid from cases of zoster fixes complement with antisera (Netter, Urbain, and Weissmann-Netter, 1924, Bedson and Bland, 1929) The test is extensively used in variola, with vesicle fluid or crusts the source of antigen (see below).

Vaccine calf lymph can be used as antigen with antivaccinial or variolous sera (Jobling, 1906, Dahm, 1909, Kolmer, 1916) The antigen is resistant to boiling (Glaser and Koref, 1928, Lurje and Wolkowitsch, 1928).

Simple tissue suspensions can be used Thus Bedson and Bland (1929) used a 5 per cent suspension of tissue infected with vaccinia or herpes in M/50 phosphate buffer, clarified by light centrifugation or prolonged standing A 5 per cent. suspension of mouse spleen infected with psittacosis was used by Bedson (1933). A suspension of monkey parotid has been used in work with mumps virus

In veterinary work, Berkefeld filtrates of tissue infected with foot-and-mouth virus have been found to fix complement with immune sera (Lourens, 1909), unfiltered vesicle fluid has also been used (Mezincescu, Baroni, and Calinescu, 1923, Urbain, 1927).

2 Washed preparations of elementary bodies can be used, e g, in vaccinia, influenza or psittacosis

Preparations containing specific soluble (flocculable) substances can be used as sources of antigen, e g, in vaccinia, influenza, lymphocytic choriomeningitis, and mumps

3. Virus grown in tissue culture can form a source of antigen, e g, for vaccinia (Gilmore, 1931)

4 Virus grown in the egg yields a very suitable source of complement fixing antigen Thus, the chorio-allantoic membrane can be used with vaccinia virus. In psittacosis, lymphogranuloma, and other members of this group, antigen can be prepared from the yolk sac (see Section 7) The complement fixing antigen of lymphogranuloma can be enhanced by treatment with phenol, urea, ether, or boiling (see Chapter LXXII) Allantoic fluid can be used as a source of antigen, e.g in influenza (see Chapter LXII), or mumps (see Chapter XXIV). Amniotic fluid can also be used, e.g, in mumps

Irradiated whole embryo antigens have been used with equine encephalomyelitis

Yellow Fever

Hughes (1933) showed that the sera of monkeys which had recovered from the disease developed a precipitin capable of reacting with a precipitinogen occurring in the blood of monkeys during the acute phase of the disease. This precipitinogen, which was associated with the albumin fraction of the serum, was not the virus of yellow fever *per se*. The amount varied with the severity of the infection, and it was independent of the virus neutralizing antibody; it disappeared after the monkey recovered from the disease, and was thought to be responsible for stimulating the development of precipitating antibodies in the sera of animals after an attack of yellow fever.

A similar precipitin was found in convalescent human sera, which reacted with the precipitinogen occurring in the blood of infected monkeys

Serum derived from a monkey moribund from yellow fever was filtered through a Seitz filter, and antiserum obtained from a monkey which had recovered from a virulent (Asibi) strain of yellow fever was likewise treated The sera were then mixed in a test tube, incubated at 37° C. for 2 hours, and examined for the presence of cloudiness The ring technique was also tried by putting undiluted antiserum in the foot of a test tube (2 mm. in diameter) with the aid of a capillary pipette, and this was over-floated with serum derived from an ill animal. The two fluids were next incubated at 37° C. for 2 hours, and the results thereafter read in artificial light with the aid of a dark background A positive result was signified by the formation of a ring of turbidity at the fluid interface, while in the control test, in which normal monkey serum was substituted for antiserum, no such reaction occurred.

COMPLEMENT FIXATION IN THE STUDY OF VIRUSES

General Technique

The technique of performing a complement fixation test, using a virus suspension as antigen and its homologous antiserum, is little different from that of carrying out any routine complement fixation test (Mackie and McCartney, 1938, Browning and Mackie, 1937). The main difference lies in the fact that since viruses cannot be grown in large amounts on culture media like ordinary bacteria, antigen consisting of infected tissues must be employed. The use of the latter presents two disadvantages—the first is that it necessitates the use of an additional antigen and serum control. The second drawback is that since the concentration of virus in the tissues may be relatively low, its complement binding potency may be correspondingly feeble, so that a finely balanced test must be set up and sufficient time must be allowed for union of antigen and antibody to take place (Bedson, 1928)

The modes of preparing antigen have also received attention, different methods being used according to circumstances These are referred to below under their respective diseases The hemolytic system employed is similar to that used for the Wassermann test, and has usually consisted of a 3 or 5 per cent. suspension of either sheep or ox erythrocytes sensitized with about 5 m h d of homologous immune body Guinea-pig complement is universally employed, and this can be used either fresh or preserved by Sonnenschein's (1930) method (Mackie and McCartney, 1938), or else desiccated complement (Craigie, 1931) may be substituted It is well to use the mixed serum of several animals The minimum hemolytic dose of complement is determined in the usual way by titrating with sensitized corpuscles to be used for the particular experiment, and the test can be performed by the addition of a fixed volume of serum-antigen mixture to varying amounts of complement, or vice versa Thus, certain workers have preferred to use a fixed amount of complement in their tests, usually about 3 m h d , and add varying dilutions of serum, whereas others have chosen to employ a fixed volume of serum with

[illegible]

Rift Valley Fever

Broom and Findlay (1932) have demonstrated the existence of specific complement fixing antibodies in the sera of humans and animals recovered from the disease. The antigen used was either a 2 per cent. saline extract prepared from fresh infected mouse or rat liver, or from similar tissues which had been desiccated over phosphorous pentoxide For the test, three different dilutions of the antigen suspension were used, namely, 0.25 c.c of 2 per cent., 1 per cent , and 0 5 per cent. [illegible] for a further 10 minutes and the results then read. The serum control consisted of normal human or animal serum, the antigen control being normal mouse or rat liver. In addition, an extra control was included in which a known positive serum was tested against infected liver tissue as well as normal liver.

Dengue

Partial success with complement fixation reactions has been claimed by Simmons, St. John, and Reynolds (1931) who at first tried to perform the test with antigen consisting of infected human blood, or the liver or spleen of infected *Macacus philippinensis* monkeys, but with negative results. Later, however, they were able to demonstrate fixation with antigen consisting of ground-up infected Aedes mosquitoes, for which purpose 279 insects were suspended in 95 per cent. alcohol, allowed to stand for 12 days, centrifuged, and the supernatant fluid diluted to make a 1 10 suspension in physiological saline

With such antigen, Simmons and his co-workers were able to show the presence of specific complement fixing antibodies in the sera of individuals who had suffered from dengue fever, the reaction being found positive from the first to the ninth day of the patient's illness

Yellow Fever

Frobisher (1929) and Davis (1931) have demonstrated that the sera of persons or monkeys after recovery from an attack of yellow fever develop specific comple-

It is reported that nonspecific fixation is lessened if sera are inactivated at 60° C for 15 minutes when using such antigens (Brown, 1947).

5. In work with the neurotropic agents (see Section II), brain tissue treated with ultraviolet light has been used as a potent yet noninfective source of complement fixing antigen. Antigens can also be prepared by freezing and thawing (see below).

6. Koktoantigen or boiled infected brain tissue was used as antigen for the complement fixation test by Torikata (1917), Nakagawa (1924), and Takaki, Bonis, and Koref (1926). Their method was as follows Brain tissue infected with a neurotropic virus preserved for 10 days or longer in 50 per cent. glycerin was ground up in 0 85 per cent. sodium chloride to yield a 10 per cent. suspension of brain tissue. This material was boiled for 30 minutes in a water bath, allowed to stand for 12 to 24 hours, sharply centrifuged, and the supernatant opalescent fluid used as antigen in the tests

Gildemeister and Heuer (1928) have criticized the findings of Takaki, Bonis, and Koref (1926) for, although the former agreed that complement fixation occurred between antivaccinial serum and homologous brain "koktoantigen," they questioned the specificity of the reaction as claimed by Takaki and his colleagues in respect of herpes virus Gildemeister and Heuer pointed out that normal brain tissue occasionally produced nonspecific complement fixation and, moreover, owing to the unreliability of such tests when performed on experimental animals, they expressed doubts concerning its practical value as a diagnostic reaction in man

The complement fixation test has also been performed in psittacosis with boiled antigen by Bedson (1937). Material was prepared as follows. A heavily infected mouse spleen was suspended in 5 0 c.c. of M/50 phosphate buffer solution of pH 7.6, and allowed to sediment for 24 hours in the refrigerator; the supernatant fluid was removed and centrifuged for 1½ hours in the angle centrifuge; the supernatant fluid was discarded, and the deposited material resuspended in 5.0 c c. of phosphate buffer, following which coarse fragments were removed by light centrifugation, the suspension was finally steamed for 30 minutes and employed as antigen in the test The control antigen consisted of normal mouse spleen

Boiled antigen prepared by this method was found useful for demonstrating the presence of complement fixing antibodies in the sera of human cases of psittacosis, and Bedson found that heating not only increased the sensitivity of the material, but also made it easier to preserve and safer to handle

In the case of herpes virus, however, heated antigen has given disappointing results, and Bedson and Bland (1929) reported that heating greatly diminished the antigenic activity of tissue extracts prepared from infected guinea-pig feet

7. Lyophilized benzene-extracted antigens prepared from brain or chick embryo show less tendency to give nonspecific reactions (Cox, 1948)

SOME REPRESENTATIVE COMPLEMENT FIXATION TESTS

Smallpox

Craigie and Wishart (1936) prepared antigen by macerating 40 mgm crusts in 0.2 c c 8 5 per cent. sodium chloride with a glass rod, 1 8 c c. of distilled water were added, and after centrifugation, the supernatant fluid was used as antigen The following scheme was recommended (see also p 370)

The complement employed for the reaction consists of guinea-pig serum which has been dried from the frozen state (see Craigie, 1931) Since prolonged cold room fixation is necessary, it will be observed that a special control is included, in order to ascertain whether the different dilutions of complement employed have deteriorated during the period of 16 to 18 hours' fixation

The serum employed is antivaccinial serum derived from rabbits immunized against vaccinia virus

day. Brains from all mice are emulsified in 10-fold the weight of diluent consisting of 2 per cent. normal guinea-pig serum (heated at 56° C. for 30 minutes) in normal saline, emulsification is performed in the Waring blender. The suspension is kept overnight in the refrigerator, and then centrifuged at 2,500 r.p.m for 30 minutes. The supernatant fluid is placed in 10 c.c. amounts in lusteroid tubes, and frozen and thawed by dipping alternately in CO_2 alcohol and water at 37° C This process is repeated until flocculation is noted, usually 4–5 times Finally, the extract is centrifuged *in an angle head machine at 7,000 r p m. for 1 hour; the supernatant con*stitutes the antigen after ad[illegible] used for as long as 4 months after [illegible] been prepared from the following [illegible] uelan encephalitis, Russian, louping-ill, Japanese B, West Nile, St. Louis, Theiler's GD VII strain, and lymphocytic choriomeningitis. These antigens are highly virulent Inactivation by [illegible] at 60° C. for [illegible] case of Venc[illegible] precipitate, ir[illegible] for at least 2 years

(2) The use of tissue extract as antigen and as an immunizing material for the production of antisera requires careful control For it is known that fresh normal *sera fix complement with a component in normal tissue extracts, which is sedi*mented at high speed, brain tissue injected in heterologous animals induces the formation of organ-specific antibodies. Accordingly, Casals immunizes animals with homologous tissue, and eliminates nonspecific fixation by centrifuging antigens at sufficiently high speed to sediment most of the normal tissue component responsible, or by inactivating the sera at 60–65° C. which destroys the normal serum component without affecting specific antibody

Animals are injected peritoneally on 2 occasions with 10 per cent formolized brain suspension, followed within 10 days by a peritoneal injection of live virus diluted 10^{-2}, repeated every 4–5 days. Within 4–6 weeks, most animals develop a high titer of antibodies Human sera which are positive in the Wassermann test give, as a rule, a nonspecific reaction with brain extracts This can be overcome by heating the sera at 65° C. instead of 60° C for 20 minutes.

(3) A preliminary titration of complement is made in saline, and two units are used in the test. Another titration is set up in the presence of antigen and saline solution.

(4) In the test, inactivated sera are diluted twofold (½, ¼, ⅛, 1/16 being usual), and 0 25 c c quantities are used. Then 0 25 c.c of antigen is added plus 2 units of complement in 0 5 c c Tubes are incubated at 2–4° C. for 18 hours The hemolytic system consists of 3 per cent sheep cells plus 3 units of rabbit antisheep hemolysin, and is added in 0 5 c c quantities The tubes are then incubated at 37° C. for 30 minutes

The same test can be applied in the case of an unknown antigen to be identified

(5) Casals describes certain additional safeguards Human blood should be drawn with aseptic precautions after fasting for several hours, and should be centrifuged after ½–1 hour at room temperature. Merthiolate may be added When sera cannot be tested shortly, they should be frozen They should be inactivated *at 60° C for 20 minutes, or at 65° if there is nonspecific fixation*

Importance of Adequate Controls

It cannot be too strongly emphasized that all serological tests such as complement fixation, agglutination, or neutralization tests, should be carefully controlled if the results are to be of value As alluded to earlier in this chapter, the subject demands particular attention in the study of human virus infections, since these agents are only cultivable along with living cells and the presence of the latter may

ment fixing antibodies. An antigen suitable for the test has been prepared by Frobisher (1931 *a*) according to the following procedure. The livers of several rhesus monkeys which had died from yellow fever were excised, freed from adventitious tissue, weighed, cut into small fragments with scissors, and ground in a mortar with sand to form a paste. This was then spread over the surface of a flat dish, placed in a desiccator over sulphuric acid, dried *in vacuo* for 18 to 24 hours, and the desiccate placed in hermetically sealed containers and stored in a refrigerator until required. Although saline suspensions of such material were found to act as an efficient antigen, better results were obtained using dried *liver tissue from which the fat had been removed. This was done by placing* the material in a Soxhlet apparatus and extracting the fat by treating it with ether for 8 hours or longer. The antigen was now prepared from the fat-free liver substance by first treating it with hypertonic salt solution and then diluting the mixture before use. To a measured bulk of tissue, about one-half of its weight of a 9 per cent solution of sodium chloride was added, allowed to macerate for 4 to 24 ... 0 09 per cent sodium chloride by addition of ... minutes, and the supernatant fluid passed through ... being used as antigen for the test.

Technique. Frobisher (1931) employed the following method. Sera to be tested were inactivated by heating at 56° C. for 30 minutes, 0.2 c.c. was placed in one test tube, and 0 1 c c. plus 0.1 c c of saline added to another, followed by the addition of 0 2 c.c. of diluted antigen to each tube. In a third tube 0 2 c c. of serum plus saline was placed. To all three tubes 2 m h d of guinea-pig complement were added The mixtures were then incubated at 37° C. for 1 hour, at the end of which 0 4 c c. of a hemolytic system consisting of 5 per cent sheep erythrocytes sensitized with 2 units of sheep antibody was added. The test was replaced in the incubator at 37° C. for a further period of 30 minutes, and the result read at the end of this time, or at such time as the controls showed complete lysis.

Psittacosis

The complement fixation reaction has been proved a valuable aid to the diagnosis of suspected cases of this disease (Bedson, 1935). The antigen employed for the reaction consists of a 5 per cent. saline suspension of virulent mouse spleen, *which has been allowed to stand in a refrigerator at +4° C for one week, in order* to annul any traces of natural complement (or alternatively, it is heated at 56° C for 30 minutes), and 0 1 c c bulk used for the test Boiled antigen was also shown to be effective by Bedson (1937) The patient's serum to be examined is made up 1 1 to 1 8 and 0 1 c c of each dilution employed Two m h d of complement are used throughout the test The mixtures are incubated at room temperature for 2 to 3 hours, 0 2 c c of sensitized cells added, the tubes placed in the water bath at 37° C. for 30 minutes, and the reaction read at the end of that time Bedson points out that the specific complement fixing power of these human psittacosis sera is of a low order and that a finely balanced test is essential to elicit the reaction Rigorous controls are also necessary to eliminate false reactions The reaction has been found to be positive as early as the twelfth day, and as late as the fifth week of the patient's illness

Neurotropic Infections

Casals (1947), who has had extensive experience of the complement fixation reaction in neurotropic virus infections, describes recent modifications in his technique

(1) To prepare antigens, 3- or 4-week old Swiss-W mice are inoculated cerebrally with 10^{-2} dilution of virus On the last day of the incubation period, the animals are placed in the icebox, and survivors are sacrificed on the following

this principle in order to enhance the amount of complement fixed in tests with antivaccinial sera, but the results were not satisfactory Later, Mackie and Finkelstein (1930) investigated the phenomenon of complement fixation produced by the interaction of normal serum with bacterial suspensions, and from their work they found that the normal sera of various mammals (e g, man, ox, sheep, horse, pig, white rat, rabbit, and guinea-pig) possessed the property of fixing complement with a wide variety of different bacteria.

These observations are of some interest because previously, Schultz, Bullock, and Lawrence (1928) suggested that positive complement fixation, using antivaccinial serum and vaccinial antigen prepared from infected rabbit skin, was in reality a nonspecific effect attributable to the existence of contaminant bacteria occurring in the antigen Schultz's allegations were subsequently reinvestigated by other workers, but received no support (Craigie and Tulloch, 1931).

In conclusion, we should like to add that, although specific complement fixing antibodies have been demonstrated in a great many virus diseases, these reactions are as a whole so delicate that the execution of such tests demands the utmost care and attention.

per se cause certain nonspecific effects For example, although it is well known that many viruses function as efficient antigens in specific complement fixation reactions, yet earlier literature *on this same subject contained many contradictory* reports. In reference to this point, Parker and Muckenfuss (1933) have pointed out that some of the results reported were useless, either because they were insufficiently controlled, or else because they did not contain sufficient data For instance, when attempting to prepare a hyperimmune guinea-pig antivaccinal serum by inoculating the animal with vaccinia virus grown in rabbit testis, the experiment should be controlled by preparing another serum derived from a separate guinea-pig which has received a similar number of doses of normal rabbit testicu*lar extract The serum of a normal guinea-pig, if employed* as a *control* under such circumstances, would obviously be an inadequate check. This control is essential, [illegible] ment fixation, [illegible] inoculation [illegible] onsisting of normal healthy testis tissue should also be incorporated in the experiment in every case.

The state of our knowledge regarding the extent to which the parenteral injection of tissues derived from one species of animal into those of another gives rise to various immunological effects is as yet incompletely understood; for example, in the case of the Forssman reaction, the inoculation of a rabbit with the kidney tissue of a guinea-pig leads to the production of an hemolysin in the rabbit's serum for sheep erythrocytes. A hypothetical instance in which this phenomenon would interfere with the performance of a complement fixation test applied to a virus disease would be as follows if a rabbit was immunized with a virus contained in an infected guinea-pig's kidney, the rabbit's serum would not only develop complement fixing antibodies for the particular agent introduced, but would simultaneously produce an hemolysin for sheep cells Under such circumstances, an hemolytic system consisting of sensitized ox cells would have to be substituted for sheep cells. During the course of serological studies in connection with viruses, a careful watch should always be kept for the appearance of phenomena of a similar type, and no positive result should be accepted unless it has been proved beyond doubt that the effect is specifically due to the antigenic properties of the virus itself, and not one peculiar to the tissues of the animal in which the virus has been cultivated

In their carefully controlled experiments on influenza virus, Fairbrother and Hoyle (1937) have revealed the practical importance of this point, for, when they endeavored to apply the complement fixation test to ferret sera, they found from their control experiments that the complement fixation which occurred between anti-influenzal ferret serum and influenzal mouse lung was nonspecific in character, *as the same effect was obtained with normal mouse lung as antigen* Likewise the work of Gildemeister and Heuer (1928) showed that normal rabbit brain tissue could behave in a similar manner, and Hildebrand (1936) also proved that rabbit serum and normal human lymphatic glands could act in the same way. In the past ten years the researches of Bedson, Casals, Craigie, Fairbrother, and others, have improved the technique of complement fixation reactions applied to the study of viruses, and their results have indicated the great possibilities of such tests

The principal obstacle offered to the future development of this work, along lines which may be of practical utility in human diagnosis, still remains that of nonspecific complement fixation caused by tissue proteins As an academic problem the subject of nonspecific complement fixation is a complex one, and this has been intensively investigated *by Mackie and Finkelstein (1928) who have made a special* study of nonspecific complement fixation produced by the interaction of normal serum and certain nonantigenic substances Mackie and Finkelstein's work has also drawn attention to the possibility of increasing the amount of complement fixed by the addition of cholesterol to the antigen Gilmore (1931) endeavored to utilize

this principle in order to enhance the amount of complement fixed in tests with antivaccinial sera, but the results were not satisfactory Later, Mackie and Finkelstein (1930) investigated the phenomenon of complement fixation produced by the interaction of normal serum with bacterial suspensions, and from their work they found that the normal sera of various mammals (e g., man, ox, sheep, horse, pig, white rat, rabbit, and guinea-pig) possessed the property of fixing complement with a wide variety of different bacteria.

These observations are of some interest because previously, Schultz, Bullock, and Lawrence (1928) suggested that positive complement fixation, using antivaccinial serum and vaccinial antigen prepared from infected rabbit skin, was in reality a nonspecific effect attributable to the existence of contaminant bacteria occurring in the antigen Schultz's allegations were subsequently reinvestigated by other workers, but received no support (Craigie and Tulloch, 1931)

In conclusion, we should like to add that, although specific complement fixing antibodies have been demonstrated in a great many virus diseases, these reactions are as a whole so delicate that the execution of such tests demands the utmost care and attention.

CHAPTER XII

TISSUE CULTURE IN THE STUDY OF VIRUSES

Certain tissue cells will readily grow *in vitro* if adequately supported, nourished, and incubated, and such tissue cultures may be used in the study of viruses in various ways. Thus, they have been used in the study of virus inclusion bodies and life cycles, as a specialized culture medium to secure proliferation, and in the study of certain aspects of virus immunity. Before these applications can be considered, however, the methods used to secure growth of normal cells must first be discussed.

For fuller details than can be given here, a modern textbook on tissue culture should be consulted (e.g., Cameron, 1935; Parker, 1938).

Source of Cells for Tissue Culture

Epithelium is most readily obtained from the rabbit's cornea as follows: The [illegible] can be detached by slicing with the flat of the knife. These small pieces are placed in a covered bath of Tyrode's solution, and incubated at 37° C. until required.

Fibroblasts can be readily obtained by culturing small pieces of such parenchymatous organs as the lung, liver, kidney, or heart. We have obtained excellent growths of fibroblasts from mouse lungs.

Testis. Minced rabbit testis is frequently employed; mouse testis may also be used.

Chick embryo cells. Epithelium may be obtained from the lung, and fibroblasts from the leg muscles, of the chick embryo. The whole embryo is frequently used in media of the Maitland type.

Mouse and rat embryos may be used. They are removed 2 to 3 days before term and finely minced.

Materials required for Tissue Culture

Slides measure 3 by 1½ in. with a central hollow of 1 in. diameter, and should be wrapped in Kraft paper.

Coverslips should be of thickness number 1 and contained in a small tin or glass jar.

Pasteur pipettes have a very fine point and are contained in a tin.

Watch-glasses are wrapped singly in Kraft paper.

Instruments: a selection of seekers, forceps, and probes is contained in a tin box.

All the above are sterilized in the hot-air oven.

Glass tubes measure 3 in. long by ½ in. in diameter, they are corked at either end by a rubber bung, and should be sterilized by autoclaving.

Incubator: this should be set at 37° C., contain numerous rigid trays, and have a moist atmosphere.

Tyrode's solution is prepared as follows: sodium chloride, 8 gm.; potassium chloride, 0.2 gm., dextrose, 1 gm., acid sodium phosphate, 0.05 gm., sodium carbonate, 1 gm., magnesium chloride (5 per cent. anhydrous salt), 4 c.c., calcium chloride (5 per cent. anhydrous salt), 4 c.c., distilled water, 1,000 c.c.

This strongly alkaline solution is adjusted to pH 7.4 by addition of a 5 per cent. solution of 85 per cent. phosphoric acid, approximately 1 to 1.5 c.c. being required

per 1,000 c.c. of solution. Acidity should be corrected by addition of 10 per cent. sodium carbonate solution. The solution is finally sterilized by filtration through a single disk of a Seitz (EK) filter at 30 mm of mercury, it is then distributed aseptically into small bottles and tubes, and stored in the ice chest until required.

Sealing mixture consists of vaseline, 7 parts, and paraffin (m.p 54° C.), 1 part, it is sterilized by placing a small screw-topped bottleful in boiling water, or on a hot plate

Nutrient fluids: plasma. Chicken plasma is recommended, and is obtained by bleeding a young bird which has been starved for 24 hours The wing is carefully plucked and sterilized, and the vessels in close relation to the humerus are located Two ligatures about ⅓ in. apart are then passed loosely round the vessels, which are cut in between these points As the blood flows out, it is received into a series of test tubes containing heparin to prevent clotting. After sufficient blood has been collected, the ligatures are tightened and bleeding arrested. The bird should receive a large dose of saline solution given subcutaneously to make up for the loss of fluid. Rabbit plasma may also be used, the heparinized blood being centrifuged, and the plasma separated.

It has been found that mammalian plasma can be stored for a long time in the ice-chest, if treated in the following way (Baroni, 1930, and personal communication) Whole blood is mixed with Tyrode's solution (10 to 15 times concentrated), and then centrifuged The plasma is separated and stored. When serum is required for use, 1 part of plasma is mixed with 3 or 4 25 parts of distilled water, when a clot forms Plasma (and embryo extract) may be frozen and dried *in vacuo* (Hetherington and Craig, 1939).

Rabbit serum. A rabbit is heart-punctured, and the blood allowed to clot, the serum being separated after "ringing" and centrifugation. Serum can be stored in the lyophil form (Hetherington, 1944).

Spleen extract. A freshly removed rabbit's spleen is ground up with approximately 10 parts of Tyrode's solution. After low-speed centrifugation for ¼ hour the clear supernatant is removed from the deposit, and constitutes spleen extract, which may be stored in the ice chest if so desired. We recommend this extract, although embryo extract can also be used.

Embryo extract. The egg shell of an 8- to 10-day chick embryo is carefully disinfected with spirit and iodine, and when dry is partially opened with a dental drill The embryo is removed, then minced and ground-up with 3 c c. of Tyrode's solution. After slow centrifugation for a few minutes, the supernatant fluid is withdrawn to constitute embryo extract

METHODS OF TISSUE CULTURE FOR THE STUDY OF VIRUS INCLUSIONS

1. The Clotted Plasma Method

(a) Preparation.

For speed and accuracy the following routine is recommended

1 Three working places are desirable, the workers sitting side by side

2 The worker on the left is responsible for unwrapping sterile hollow-ground slides, *ringing round* the hollow with sealing mixture (kept melted by a water bath or electric hot-plate), and passing them on to the central worker

3. This worker mixes up the nutrient fluids in the following proportions chick plasma, 2 parts, rabbit serum, 2 parts, and spleen extract, 1 part, this is carried out by pipetting the correct number of drops of each material into one of the sterile watch-glasses The contents are mixed by sucking up once or twice in another sterile Pasteur pipette

4 Meanwhile, the worker on the right, working with his hands inside a cabinet,

is placing 2 to 3 squares of cornea, or other tissue, onto sterile coverslips These pieces of tissue are referred to as "explants"

5 The central worker, working through the side door of the box, covers each piece of tissue with a drop of nutrient fluid, and then picks up each slip with a vaselined slide. These are left upside down for a few minutes, until the plasma clots, when they are inverted and placed on trays in the incubator.

(*b*) **Progress.**

Cultures may be examined microscopically after 36 to 48 hours, when, if successful, a considerable growth should be apparent Epithelium spreads out as a continuous sheet around the explant, and has a very regular growing edge. Each cell is roughly polyhedral and rather granular, by appropriate methods much of this granularity can be shown to be due to fat. Fibroblasts grow out more in the form of individual strands and filaments, thus giving the edge of the culture an irregular appearance Cells growing
growing vertically appear
to the explant will probal
of no consequence as pure cultures are not essential in virus work

Cultures may be infected at the time of setting up, or later. Bland and Robinow (1939) infected their cultures after about 3 days' growth, when the culture medium had partly liquefied In these experiments, the cultures were washed with saline to remove excess virus inoculum, and then nutrient fluid was added and the growths remounted.

(*c*) **Subcultivation.**

Growth should occur for 5 to 7 days, before the nutrient fluid is exhausted, the results of most virus experiments should be evident by then, but occasionally it may be necessary to subculture If so, the slip is removed from the slide, and placed, culture upward, on a dark background. The clot is then cut through the center with a sterile razor blade, down to the glass The old clot is picked off, and the two culture fragments are floated out in a warm bath of Tyrode's solution Two fresh cultures can then be prepared by covering these pieces with nutrient fluid on a coverslip, as already described.

(*d*) **Histological examination.**

Cultures embedded in a solid plasma clot are difficult to stain, as fixation frequently results in the formation of an insoluble precipitate The following method, which dispenses with previous fixation, can be recommended

1 HEMATEIN AND EOSIN METHOD (see Rhodes, 1937).

Solutions required

Hematein methylated spirit, 75 c c , glacial acetic acid, 5 c c., formalin, 10 c c , Mayer's acid hemalum, 5 c c.

Alcoholic eosin saturated solutions of alcoholic eosin and methylated spirit, equal parts.

Procedure

1 Remove slip, float, culture down, in a bath of hematein for 10 minutes
2 Wash in methylated spirit and then in tap water
3 Dehydrate partially with methylated spirit and absolute alcohol.
4 Counterstain in alcoholic eosin for 1 minute.
5 Wash with absolute alcohol, and leave in xylol till dehydration is complete. Mount in balsam.

This method stains nuclei blue and cytoplasm pink A number of other methods may also be used, most of these involve preliminary fixation

2. PRELIMINARY TREATMENT WITH WARM FLUID

It is said that if the slip is floated, culture downward, in a bath of warm Ringer's or Tyrode's solution for approximately 30 minutes, the plasma becomes detached, and even if not, subsequent fixation and staining will be rendered easier.

3. FIXATION METHODS.

Fix the culture, after the above treatment, in iodine vapor, formalin, or osmic acid Another method is to fill up the hollow of the slide with 2 per cent. formalin in saline, and then float the slip, culture downward, on the surface.

4 DEHYDRATION AND EMBEDDING.

Thereafter, the culture may be sliced off the slip with a sharp razor blade, dehydrated, cleared, and embedded in paraffin Sections are cut parallel to the axis of the slip and may be stained by any suitable method

5 FISCHER'S METHODS (see 1925).

Method (a). Procedure.

1. Fix in 2 per cent formalin in Ringer's solution for 1 hour.
2. Wash in running water for 3 hours, and distilled water for 1 hour
3. Place in 10 per cent. aqueous hematoxylin for 10 to 12 hours, wash for ½ hour.
4. Treat with 50, 75, 95 per cent. alcohols for 5 minutes each.
5. Place for 10 minutes in each of the following mixtures: 95 per cent. acetone and 5 per cent. xylol, 70 per cent. acetone and 30 per cent xylol, and 30 per cent acetone and 70 per cent. xylol
6. Clear in xylol, and mount in balsam

Method (b) Solution required.

Saturated alcoholic solution of methylene blue, 30 c.c., 1/10,000 potassium hydroxide, 100 c c, ripen in incubator for 1 month

Procedure

1. Fix and wash as above
2. Apply distilled water for 5 minutes.
3. Pour on methylene blue, heat till steam rises, leave for 15 minutes, wash
4. Dehydrate and clear as above, except that for alcohols 1 minute is enough, and for acetone-xylol mixtures 2 minutes each.

6 STRANGEWAYS'S METHOD (see 1924).

Solutions required.

Acetic alcohol 0 5 per cent glacial acetic acid in 70 per cent. alcohol
Iron alum 2 5 gm iron alum in 100 c c distilled water

Procedure.

1. After treating in warm fluid, as above, place slip in a watch-glass of acetic alcohol for 5 minutes, wash in running distilled water for 5 minutes
2. Apply iron alum for 30 minutes, wash as in 1
3. Float slip, culture down, on the surface of ½ per cent. watery hematoxylin for 5 minutes at 37° C, wash for 2 to 3 minutes.
4. Differentiate in iron alum, control microscopically, wash as in 1.
5. Mount in Farrant's mountant.

7. Stain for Fat (Strangeways, 1924).

Procedure.

1. Proceed as in above method, but after differentiation in alum and washing, place in saturated solution of either Scharlach R or Sudan III for 5 minutes, wash in water.
2. Mount in Farrant's mountant

8 Bland and Robinow's (1939) Method

Procedure.

1. Float cultures (on glass mounts) for a minute on warm saline, and then expose to a strong concentration of osmic acid for 5 to 6 minutes.
2. Harden in 70 per cent. alcohol for 5 minutes, wash in distilled water.
3. Stain overnight in Hollborn's Giemsa (20 drops to 15 c.c. buffered distilled water, pH 6 9).
4. Differentiate in acetone-xylol mixtures, before this, weak acetic acid should be applied to correct over-red preparations.

2. Miyagawa's Method (Miyagawa *et al*, 1936)

This is a variation of the usual clotted plasma method, and has been used to study the development of the granulocorpuscles of lymphogranuloma inguinale.

(*a*) *Preparation.*

Guinea-pig plasma (heparinized) and mouse spleen extract are mixed in the hollow of a hollow-ground slide, this forms a thin film, which soon clots Fragments of normal mouse testicle or spleen are embedded in the clot, alongside fragments of a mouse brain infected with LGI The whole is then covered with more spleen extract, sealed, and covered with a mica slip.

(*b*) *Progress.*

New cells can be observed to grow out of the normal fragment, which gradually becomes infected with virus from the neighboring brain tissue.

(*c*) *Subcultivation*

This is carried out by removing the liquid extract and infected brain tissue, washing the testicle or spleen fragment in Tyrode's solution, and embedding it in another plasma clot Some healthy testicle or spleen is now implanted beside this infected fragment, and the whole covered and sealed as before

(*d*) *Histological examination*

The liquid extract is removed, the tissue fragments are then fixed in formalin, and stuck to an albumenized slide Giemsa's stain shows typical granulocorpuscles in the newly formed cells at the edge of the growth.

3. The Liquid Culture Method

(*a*) *Preparation*

These cultures are set up in the same way as in the clotted plasma method, except that the nutrient fluid varies. Thus, the cells are grown in mixtures of serum and Tyrode's solution, or plasma and serum, without added extract Generally speaking, the growth of cells obtained by this method is poor. The method must, however, be used for micromanipulation studies, as the needles cannot work through clotted plasma

(b) Progress.

Progress is followed microscopically, great care being taken not to shake or jolt the culture.

(c) Subcultivation

The exhausted nutrient fluid is simply sucked off, and replaced with a fresh supply.

(d) Histological examination.

To those methods already mentioned in previous sections may be added one other:

GIEMSA'S METHOD (Bland and Canti, 1935).

Buffer solution required: potassium dihydrogen phosphate, 1 gm; disodium hydrogen phosphate, 2 gm, distilled water, 1,000 c.c.
Stain: 2 drops of Giemsa in 1 c.c. of buffer solution.

Procedure

1. Gently wash culture in saline, and fix in methyl alcohol for 5 minutes.
2. Rinse in buffer solution, remove, and discard the center of the explant.
3. Stain for 24 hours at room temperature.
4. Differentiate in acetone, clear in xylol, and mount in balsam.

4. The Tube Culture Method

This method has been used in studies on vaccinial inclusion bodies (Rivers *et al*, 1928–9, 1929 *b*; Rhodes and van Rooyen, 1937).

(a) Preparation.

A rabbit's eye is freed in the orbital cavity, the cornea is washed with saline, and dissected out entire. It is then cut up in a bath of Tyrode's solution into 8 to 12 squares of approximately equal size. Nutrient fluid, as used in the clotted plasma method, is then pipetted into each of a number of glass tubes to a depth of ½ in, these tubes are closed at either end by a bung When the clot has formed, a piece of cornea is placed horizontally on top, and covered with another layer of fluid. Soon the contents of the tube have formed into a solid clot, in the center of which lies the piece of cornea

(b) Progress

This can only be estimated by examining histological preparations.

(c) Subcultivation

This cannot be carried out, but the tissue should grow for at least 7 days before the nutrient fluid is exhausted

(d) Histological examination

1 Remove both stoppers, gently tap the tube, and the entire clot should slip out Fix in Helly's or other fixative for a short time

2 Thereafter, dehydration, clearing, and embedding are carried out as usual Paraffin sections are cut parallel to the sides of the tube, thus giving, in the center of the clot, a radial section of cornea

3. Sections may be stained by any desired method, e.g, Mann's stain

This method has an advantage over the slide methods, for a perfect histological preparation is obtainable Such sections show that cellular proliferation has occurred in the depths of the cornea, as well as in the superficial epithelium Thus,

the fibroblasts in the substantia propria increase in numbers, and there is considerable thickening of the epithelial layers

5. Carrel's (1923) Method

(*a*) *Preparation*

Cultures are contained in special Carrel flasks, of which various shapes have been designed. The commonest shape for bacteriological purposes is that known as Type D. The diameter of these flasks may be either 5 or 8 cm. The other shapes are. Type A, resembling D in shape, but fitted with a top opening, 3 cm. in diameter, Type B, resembling D, but fitted with two side arms, Type C has a longer neck than D, and top and bottom openings; Type E resembles D, but has

plasma, which is run uniformly

with 5 per cent. tissue extract

added) are then mixed with the plasma The fragments of tissue to be cultured are embedded in the plasma just before it clots, by using a long narrow metal spatula When the clot forms, some fluid medium is run over the surface; if the cells are epithelial or fibroblastic, use 25 per cent. tissue extract in Tyrode, and if leukocytic, use 2 parts Tyrode and 1 part each of serum and tissue extract (Cameron, 1935).

(*b*) *Progress and* (*c*) *Subcultivation.*

The fluid requires to be changed every 2 to 5 days, to do this, carefully flame the neck of the flask, suck out the old fluid, and add fresh. When the original clot becomes exhausted a section is cut out with a spatula, the tissue dissected out and re-embedded in a new flask.

(*d*) *Histological examination.*

Sections of clot may be removed with a spatula, fixed and taken through to paraffin, excellent results being obtained after suitable staining In other cases, fixative may be poured into the flask, and the fixed tissue removed by breaking the glass.

THE STUDY OF VIRUS INCLUSION BODIES AND LIFE CYCLES

Various viruses produce inclusions when added to, or incorporated in, tissue cultures of the above types. Thus, with slide methods, lymphogranuloma inguinale (see p 775), vaccinia (see p. 344), and psittacosis (see p. 750), have been shown to form inclusions. The virus of herpes has been studied by the tube culture method and inclusion bodies described (Rivers *et al*, 1928–9, 1929 *b*). Rhodes and van Rooyen (1937), employing the same method in the study of vaccinia, found that inclusions developed Carrel's method has been used by Andrewes to demonstrate inclusion bodies in virus III of rabbits (1929 *a*, *b*), and herpes (1930)

The following method was used by Bland and Canti (1935) in their study of the life cycle of psittacosis

1. The nutrient fluid was prepared as follows 2 parts of chick plasma were mixed with 3 parts of chick embryo extract (2 5 c c. saline to each minced to days' embryo), when clotting occurred, fluid was expressed. This fluid was diluted with an equal volume of saline, and centrifuged at high speed for 1 hour, to remove refractile granules Epithelial cells were cultured directly in this fluid, but fibroblasts were first grown by the clotted plasma method, and subcultured into this later

2 Explants of the muscle or lung tissue to be cultured were mounted by Maxi-

ter) being fixed

a small amount

3. Cultures were infected by adding virus to the nutrient fluid at the onset, or

after a certain amount of growth had occurred. In the latter case, the medium was replaced by a drop of virus, and the culture incubated for 1 hour. Then the culture was re-opened, the virus washed off, and fresh nutrient fluid added.

4. Such infected preparations were examined after a further period of growth, either by Giemsa's stain, or by darkground microscopy. For the latter examination cultures were mounted as contact specimens The thick center of the culture was discarded and the slips were then inverted over a thin slide to which thin strips of coverslip were luted with distilled water.

In this study the various developmental phases in the life history of the psittacosis virus were worked out. Somewhat similar studies have been made with vaccinia (Bland and Robinow, 1939).

Merling (1945) has carried out prolonged observation on the phagocytosis of vaccinia virus by leukocytes, using fragments of cornea in Tyrode's solution on slides. Preparations were stained by Herzberg's Victoria blue 4R and examined by transmitted and darkground illumination.

Chick embryo cells grown in tissue culture can be examined with the electron microscope (Porter, Claude, and Fulham, 1945).

THE PROPAGATION OF VIRUSES

Ever since viruses were first discovered, at the close of last century, attempts have been made to culture them. Although viruses resemble bacteria in many respects, they differ radically in that they cannot be cultivated on ordinary laboratory media, however much enriched. The whole trend of modern work shows that viruses will only grow in the presence of living cells, and it has been suggested that they exhibit the most extreme degree of parasitism in nature.

Prior to 1928, a number of investigators had obtained growths of vaccinia virus in tissue culture, the usual method was to use hanging-drop preparations of embryo tissue or testis suspended in serum or plasma, with virus added. This technique was somewhat uncertain, it did not permit of large-scale operations, nor of ease and accuracy of titration. A real advance was initiated when Maitland and Maitland (1928) grew vaccinia virus in a medium containing hen's kidney and serum.

Maitland's Media

Originally, the inoculum consisted of the testis of a rabbit inoculated 4 days before with vaccine lymph, ground in sand, with M/50 phosphate (pH 7.6) added After centrifuging, the supernatant fluid (approximately 5 c.c.) was used for the primary inoculum

The kidneys of a hen were cut up with scissors and 0.66 gm. placed in a flask, 1.33 c.c. of virus inoculum (diluted 1/66 with Tyrode's solution) being added After standing in the cold room for 4 hours, 12 c.c. Tyrode and 6 c.c. hen serum were added, thus making a final dilution of virus inoculum of 1/100 Thereafter, 2 c.c. amounts were distributed into Carrel flasks (Type D), and incubated aerobically at 37° C, without caps Cultures were titrated for the content of virus by grinding with sand, centrifuging, and injecting 0.2 c.c. of dilutions of the supernatant intradermally in rabbits During four successive subcultures, virus increased approximately 25×10^6 times In these cultures it was not possible to detect any tissue growth, after 24 hours the smallest pieces of kidney had begun to disintegrate, this process of autolysis being complete by the third day.

Maitland and Laing (1930) substituted rabbit for hen tissues, they placed 0.33 c.c. of freshly minced kidney or testis into a wide tube. Vaccinial material was then added and gently mixed, 3 c.c. of serum, and enough Tyrode's solution to give a final bulk of 10 c.c., were then added (serum last). The mixture was finally distributed into Carrel flasks in 2 c.c. amounts Vaccinia would not multiply in liver or spleen cultures.

Maitland, Laing, and Lyth (1932) found that vaccinia would grow readily in minced chick embryo and Tyrode's solution without serum.

In Maitland's most recent publication, the following method is recommended (Maitland and Laing, 1941): Minced adult rabbit kidney, 0.35–0.4 gm., is added to 10 c.c. of Tyrode's solution in a small conical flask, 0.1 c.c. of virus suspension (e.g., the supernatant from a previous culture) is added. The contents are thoroughly mixed, and 2.5 c.c. distributed into Carrel flasks. Two flasks should be incubated for 7 days at 37° C. in a moist atmosphere, and then titrated. One flask is prepared for titration at once, to assess the virus titer before incubation.

To titrate cultures, the contents of flasks are decanted into a sterile mortar, sterile abrasive is added, and the contents thoroughly ground. Fivefold dilutions of the supernatant fluid (after centrifugation) are made in sterile saline and 0.2 from each c.c. is inoculated intradermally in the rabbit's back.

Other Media of Similar Type

1. *Findlay's (1928) method.* In this medium fowl-pox virus was added to the skin and brain of a 12- to 15-day chick embryo, after standing in the ice chest for 2 days, equal amounts of embryo-virus suspension were distributed into flasks containing 5 c.c. chick plasma, and incubated at 37° C. for 4 days.

2. *Smith's (1935) method.* Minced 8- to 10-day chick embryos were introduced into Carrel flasks in amounts from 0.05 c.c. to 0.1 c.c. The virus (influenza) inoculum was dropped onto the tissue, it was left for 10 minutes, and then 2 c.c. of Tyrode's solution were added. The flask was rotated to distribute its contents, and incubated at 37° C. Subcultivation was carried out by transferring 0.05 c.c. of fluid from flask to flask.

3. *Tamura's methods* (1934, 1935, D'Aunoy *et al.*, 1935). A small quantity of virus-containing material was added to 10 c.c. of Tyrode's solution, in which was either a piece of guinea-pig kidney or liver, or rabbit kidney.

4. *Dochez, Mills, and Kneeland's (1936) method.* Minced 10-day chick embryo was pipetted into two culture tubes (2 cm. diameter) in equal amounts, 10 c.c. of special peptone broth were then added (sodium chloride free, made with nontoxic casein peptone, and containing 0.1 per cent gelatin). Sufficient cysteine hydrochloride was then added to give a concentration of 1/2,000 (cysteine was prepared in 1 per cent solution, neutralized with caustic soda, autoclaved, and kept under a vaseline seal). The culture tubes were sealed with vaseline, and stored at 4° C. till required. Cultures were initiated by introducing virus-containing material (common cold) through the vaseline seal. Subcultures were carried out by transferring 1 c.c. of fluid to a fresh culture tube, at intervals of from 2 to 9 days.

5. *Li and Rivers's (1930) method* (see also Rivers and Ward, 1933 *c*). This method was introduced to grow vaccinia virus on a large scale. The medium consisted of rabbit testis, rabbit serum, and Tyrode's solution for primary growths, after subculturing, chick embryo and Tyrode's solution were substituted. The conical flask made to contain this medium was of an unusual shape, being fitted with a side ventilating arm and a gutter neck to catch condensation water. The flasks were made in two sizes to hold 17 c.c. and 6 c.c., respectively.

6. *Webster and Clow's (1936, 1937) method.* To grow rabies virus in bulk, these authors used a mixture of Tyrode's solution (9 parts) and monkey or horse serum (1 part), 4 c.c. were placed in a 50 c.c. Erlenmeyer flask, and mouse, rabbit, or chick brain added. Rat or mouse embryo, with chick plasma, may also be used (Bernkopf and Kligler, 1937).

The Roller Tube Technique

Of recent years, this technique has been adopted to secure growth of viruses by various workers: vaccinia (Feller, Enders, and Weller, 1940), influenza (Pearson and Enders, 1941), and psittacosis (Morgan and Wiseman, 1946).

Tissue fragments are embedded in plasma which is distributed over the wall of a test tube. Nutrient fluid is added, and the tube rotated in a horizontal position at 37° C.

The following method is that described by Feller, Enders, and Weller for the growth of vaccinia.

Tissue. Minced whole chick embryos (minus the eyes) of 8–10 days' development, or minced hearts from 10–12 day embryos are employed.

Embryonic extract. Minced 10–12 day chick embryos (minus eyes) are extracted with an equal volume of Simms' solution for 20 minutes at 37° C. After centrifugation for 20 minutes at 2,400 r.p.m., the supernatant fluid is carefully removed and stored in the ice-box till required (For formula of Simms' solution, see below.)

Plasma and serum are obtained from adult chickens by heart puncture, and heparinizing (for plasma) or defibrinating (for serum).

Assembling cultures Clean 20×150 mm. pyrex test tubes are used, and 5 drops of plasma spread over the lower ⅔ of the surface. Fragments of minced tissue (30–50) are then added. The plasma clots, and any excess unclotted fluid can be removed. Nutrient fluid 1.6 c.c. is then added (Simms' solution, 7 parts, embryo extract, 2 parts, chicken serum, 1 part). The tube is then rocked to wet the whole surface of the tissue and plasma. The tube is sealed with a rubber stopper fitted with a short piece of pyrex tubing closed with a rubber cap.

Incubation is carried out horizontally in a rotating device turning 8–10 times an hour.

Routine attention. Each day the nutrient fluid is removed by passing a Pasteur pipette through the small pyrex tube About 20 c.c of air which has been drawn through sterile cotton-wool is injected with a syringe. Nutrient fluid, 1 6 c.c., is added, and the tube sealed and returned to the rotator. Every 5 days or so the tube is drained of fluid, and more plasma quickly distributed over the cells. Clotting is accelerated by adding a few drops of embryo extract.

Addition of virus. Virus suspension is diluted with Simms' solution, and incorporated in the nutrient fluid. The inoculum is removed from the cultures after 24 hours

Titration The tissue and plasma coagulum is scraped off and ground in a mortar with broth. Serial dilutions are made and injected in animals as indicated

Mounting is carried out by including coverslips in the tubes used for cultures

Staining The coverslips are removed and stained, or else the cultures can be fixed *in situ* in the tube, dehydrated, and the coagulum and cells scraped off later

In work with psittacosis, Morgan and Wiseman (1946) found that growth occurred equally well in: (1) a mixture of Simms' solution, 21 parts, 50 per cent chick embryo extract, 3 parts, and rabbit serum, 3 parts, or (2) Simms' solution, 2 parts, serum ultrafiltrate, 1 part The second fluid had the advantage of simplicity and freedom from extraneous tissue. The cultures were grown for 48 hours prior to inoculation Good growths occurred, and mice were protected with formolized vaccines

Solid Media

Yanamura and Meyer (1941) used a modified Zinsser solid medium for growing psittacosis:

Part 1 Distilled water, 540 c.c , Simms' solution A, concentrated, 30 c.c., agar, 16 gm.

Part 2 Horse serum, 200 c.c , Simms' solution B, concentrated, 30 c.c.

Part 1 is autoclaved at 15 lbs pressure for 30 minutes, and cooled to 45° C Part 2 is filtered through a Berkefeld candle, and warmed to 45° C The two parts are mixed, distributed in 10 c.c amounts in 20×150 m.m. test tubes, and sloped For mass cultures, 100 c.c. amounts are distributed in 200 c.c. Kolle flasks.

For routine cultures, 0.25 c.c. fresh chick embryo pulp (as dry as possible) is introduced into each slant, and infected with virus inoculum held on a platinum loop.

For mass cultures, about 3.5 c.c. of chick pulp are distributed in test tubes and mixed with the infected tissues. The infected pulp is then spread evenly on the surface of the Kolle flasks.

Tubes and flasks are sealed with paraffin over cotton wool plugs, and incubated for 3–4 days at 37° C.

Media Incorporating Serum Ultrafiltrate

A preparation known as serum ultrafiltrate has been widely used by Simms, Sanders, and others for the cultivation of viruses. The paper by Simms and Sanders (1942) gives full technical details In the preparation and maintenance of ultrafiltrate cultures for virus propagation 4 points are of special importance. The volume of tissue should not exceed 1 part in 100 of medium. The pH should be maintained at 7.2–7.6. The pH should be adjusted with CO_2 as the tissues need bicarbonate. To prevent escape of CO_2 the flasks should be plugged with rubber and not wool stoppers. Ultrafiltrate can be used in small flasks, or large 500 c.c. Erlenmeyer flasks.

Preparation of ultrafiltrate. Serum ultrafiltrate is produced from ox serum by filtration through collodion in a specially designed apparatus. The ultrafiltrate is water-clear and free from protein. Phenol red is added in suitable concentration. The ultrafiltrate is then adjusted to pH 7.0–7.2 with CO_2, sterilized by filtration through a sintered glass filter, stoppered, and stored in the icebox. For use, ultrafiltrate is diluted 1 part to 2 parts of salt solution (this dilution is known as UF/3).

Simm's physiological solutions. Various solutions are used, X7 and X6 being prepared as follows:

	20 times concentrated gm./liter	*Final composition of X7 gm./liter*
Mother solution 1		
NaCl	160	8
KCl	4.0	0.20
$CaCl_2 \cdot 2H_2O$	2.94	0.147
$MgCl_2 \cdot 6H_2O$	4.06	c.203
Mother solution 2		
$NaHCO_3$	20.2	1.01
Na_2HPO_4	4.26	0.213
Dextrose	20.0	1.00
Phenol red	0.2	0.01

X6 solution differs from X7 in the phenol red concentration being 5 times that of X7 Mother solutions 1 and 2 are prepared in 20-fold concentrations as shown in the table, and stored separately. For use, 50 c.c. of solution 1 is diluted with 900 c.c. of freshly redistilled water and autoclaved, when 50 c.c. of solution 2 are added

Another solution (Z) contains no bicarbonate, and does not change pH on exposure to air It can be used for temporary bathing or storage of tissues for short periods Z is prepared by substituting mother solution 3 for solution 2.

	20 times concentrated gm./liter	*Final composition of Z solution gm./liter*
Mother solution 3		
$NaH_2PO_4 \cdot H_2O$	0.42	0.021
Na_2HPO_4	3.8	0.190
Dextrose	20.0	1.00

Propagation of viruses in ultrafiltrate cultures. The procedure is as follows

1. The embryo organs are removed aseptically and washed twice in Z solution Tissue is then minced with scissors in fresh ultrafiltrate (diluted with Z solution) into pieces not exceeding 2 mm. The minced tissue is again washed, and then suspended in ultrafiltrate in Z solution.
2. Into each of a number of 50 c.c. Erlenmeyer flasks are placed 8 c.c. of dilute ultrafiltrate (1 part UF—2 parts X7), and each flask is stoppered with a rubber bung.
3. The flasks are opened individually and 0.06 c c. of tissue suspension is added
4. *Before closing, 5 per cent. CO_2 in air is introduced aseptically.*
5. The cultures are incubated at 37° C. for 24 hours, and are then inoculated with 0.1 c.c. of material containing active virus.

Field cultures. Sanders and Huang (1944) found that small amounts of embryonic tissues would survive in 2 c.c. of serum ultrafiltrate diluted with 2 parts of Simms' physiological solution for the following times: at 4–6° C. for 3 weeks, at 25° C. for 35 days; and at 37° C. for at least 4 weeks. These could be used as simple tissue cultures under field conditions.

The importance of pH. Huang (1943) found that in noninfected tissue cultures, the pH shifted to the acid side, and in the presence of phenol red the color changed from red to yellow within 2 hours at 37.5° C. in a partial vacuum. When tissue was heavily infected with virus such as Western equine encephalomyelitis or St. Louis, there was either very little or no change in the pH.

Cultivation of Neurotropic Viruses

Many of these agents have been grown in media consisting essentially of 10 per cent. serum-Tyrode with small portions of the following type of tissue (minced)· mouse embryo brain, whole mouse embryo, whole chick embryo, and chick embryo without nervous system

By growth in chick embryo without nervous system, Koprowski and Lennette (1946) were able to alter the neurotropic properties of West Nile virus, so that it became less virulent for mice by extraneural routes.

Attempts to grow Vaccinia in Cell-free Medium

The comparative ease with which vaccinia virus grew in Maitland's and similar media led Eagles and his associates to attempt its cultivation in cell-free media. Various series of these experiments were carried out

1 Eagles and McClean (1930, 1931) prepared a kidney extract as follows a rabbit kidney was removed aseptically and very finely minced in 3 to 4 c c of Tyrode's solution After high-speed centrifugation for 20 minutes the supernatant fluid constituted kidney extract, this was examined for cells, but none could be demonstrated The medium, designated "cell-free," was prepared from this kidney extract, vaccinia virus, and Tyrode's solution, with or without the addition of rabbit's serum, incubation was carried out in Carrel flasks. Vaccinia virus increased *considerably in amount in these cultures, e g, in one case thirteen subcultures* showed an approximate virus increase of 10^{43}, although the approximate dilution of the original seeding of virus was 10^{-22}.

2. Eagles and Kordi (1932) prepared another type of extract A rabbit kidney was chopped and ground up in 2 c c of 9 per cent (hypertonic) saline, the suspension being divided into two equal portions in centrifuge tubes One tube was left at room temperature for at least 1 hour, while the other was frozen at −12° C to −13° C. for 1 hour. The frozen tube was then thawed in water (80° C) By this means it was hoped to carry further the cellular disintegration begun by hypertonic saline. *Sterile distilled water was then added to each tube,* to make the concentration of saline normal, and centrifugation at 4,000 r.p.m. carried out for 1 hour

The supernatant fluid was likewise centrifuged, when stained films were examined no whole cells were seen, only a few possible fragments

Equal parts of fresh rabbit serum and Tyrode's solution were added to the kidney extracts to make a dilution of 1/50 of virus seeding, two parallel experiments being set up. In the first, the kidney extract treated only with hypertonic saline was used, in the second, the frozen and thawed extract was employed. The virus preparation was a fresh testicular strain of neurovaccine; it was diluted 1/50 in the medium, which was then thoroughly mixed, and distributed in 2 c c. amounts in Carrel and Rivers flasks. Incubation was carried out at 37° C. for 3 to 6 days. In one unfrozen culture, in the course of subcultivation, a total virus multiplication of 10^{20} was obtained, although the dilution of the original virus seeding was 10^{-17}. Virus increase in the frozen medium was most irregular, and it was concluded that a substance released only from fresh cells was essential for the growth of vaccinia virus.

3. Eagles (1935) has repeated some of his previous work. As kidney extract he used the unfrozen extract of Eagles and Kordi (1932). He concluded that there was poor survival of the virus in large numbers of individual flasks, and an inability to secure either growth or survival of the virus in a number of subcultures. Multiplication did, however, take place in two of the series of subcultures

This work has never been confirmed, and it is the opinion of numerous workers that vaccinia will only grow in a medium containing some living cells (e g , Craciun and Oppenheimer, 1926, Maitland, Laing, and Lyth, 1932, Rivers and Ward, 1933 *a*, *b*, Haagen, 1933) It should be noted that Rivers and Ward (1933 *b*), after treating rabbit testis and chick embryo as described by Eagles and Kordi (1932), found some cells not only alive but capable of growth.

The Mechanism of Virus Growth in Tissue Culture

There is no doubt that living cells are present in media of the Maitland and similar [illegible] nd Lyth, 1932). [illegible] d by the followi [illegible] 1929 *a*), heating [illegible] 932–33), treatment with cyanide (Breinl, 1932–33, Maitland and Laing, 1941)

Prior to the introduction of Maitland's medium, it had been shown by Parker and Nye (1925) that growth of vaccinia takes place in intimate connection with the cellular, rather than the fluid, elements of cultures They prepared cultures of virus by the slide technique, rabbit testis being embedded in the center of a large plasma clot. Tests showed the presence of virus in the testis with its corresponding absence from the plasma Later, Muckenfuss and Rivers (1930) suggested that at least one function of the living cells of a tissue culture might be to elaborate a [illegible]

in a preparation in which living cells are present.

Maitland and Laing (1941) have made some interesting observations on the growth of vaccinia in tissue cultures They find that virus increases most rapidly in the first 2–3 days, but growth continues thereafter With larger amounts of tissue, virus multiplies considerably in the first 2–3 days, and continues to increase after 4–5 days Reduction in the amount of tissue tends to lengthen the "lag period." Virus does not grow if the medium is incubated for 5 days before inoculation, yet an inoculated culture incubated for the same time still provides conditions for the continual growth of virus Evidently therefore there is one property needed to initiate growth and another to allow of virus increase The failure of a culture

to initiate growth is presumably due to cell damage. It may be that growth cannot be initiated until virus has combined with a living or surviving cell

Perhaps the factor postulated by Muckenfuss and Rivers serves to keep virus alive, while more intimate cellular contact, as suggested by the work of Parker and Nye, is needed for actual proliferation. The work of Eagles and his associates, who claim to have grown vaccinia in cell-free media, if confirmed, would suggest that a substance similar to that of Muckenfuss and Rivers can be liberated from tissue, and can support actual proliferation of virus even when the cells producing the factor have been destroyed. No such confirmation has yet been reported, however, and it appears that the growth of viruses in tissue culture is intimately dependent on the presence of living cells.

OTHER APPLICATIONS OF TISSUE CULTURE

In addition to their use in the study of virus morphology and for securing virus propagation, tissue cultures can be used for certain other purposes·

1. *Immunization.* Tissue cultures may be used to furnish a growth of virus suitable for immunization of animals, and of man Thus cultures of influenza, common cold, yellow fever, and vaccinia viruses have all been used for human immunization. Rivers and Ward (1935), for example, prepare vaccinia virus suitable for use in human vaccination

(*a*) Routine cultures were ground up in a mortar and inoculations carried out for sterility

(*b*) Bacteria-free suspensions were mixed with equal parts of sterile glycerol, and stored at temperatures below 0° C

(*c*) For use, 0 1 c.c of glycerolated culture virus, diluted 5 to 10 times with sterile saline, was injected intradermally in the skin of the upper arm or thigh, with a 27-gauge needle.

Such cultures have several advantages over the more commonly used vaccines prepared from animal tissues Thus, they can be guaranteed to be sterile, there is a minimum of foreign animal tissue present; and in an emergency a large supply can be rapidly obtained

2 *Isolation of virus* It has been reported that influenza virus may be isolated directly from patients by inoculation of tissue cultures with nasopharyngeal secretion

3 *For* in vitro *neutralization tests.* It has recently been shown that the virus-neutralizing power of immune sera can be titrated by making use of tissue cultures (Magill and Francis, 1938) These workers carried out studies with the virus of influenza, which will now be described into 50 c c Erlenmeyer flasks were pipetted 4 c c of Locke's solution and 5 drops of minced 13-day chick embryos Rabbit antiserum (0 5 c c) was then added. Finally, 0.5 c c of cultured virus was added. Incubation was carried out at 37° C for 48 hours After this time, 0 5 c.c of supernatant fluid was inoculated into a fresh flask containing saline (4 5 c c) and minced embryo (5 drops) only. Now, the final dilution of the original serum was at least 1/100 Incubation was carried out as before, and presence of virus tested by intranasal inoculation of lightly anesthetized mice If virus was destroyed in the first series, then naturally no proliferation occurred in the second, the mice being unaffected.

4. *For studying the interference phenomenon in influenza*

CHAPTER XIII

THE FERTILE EGG IN THE STUDY OF VIRUSES

THE FERTILE EGG had been studied in connection with various problems (see Goodpasture, 1938), before Rous and Murphy in 1911 made use of the developing chick embryo in their study of the Rous sarcoma. Twenty years elapsed, however, before the method was generally introduced into bacteriology by Woodruff and Goodpasture (1931), in their study of fowl-pox virus

Goodpasture and his collaborators made use of the fertile egg not only in studying virus infections (see below), but also in investigating various problems in bacteriology and serology, in the course of which they showed that the embryo could be inoculated not only on the chorio-allantois but also in the amniotic sac and intravenously. (See Buddingh and Polk, 1937, Gallavan, 1937, Gallavan and Goodpasture, 1937, Polk, Buddingh and Goodpasture, 1938, Buddingh and Polk, 1939, *a*, *b*)

Eggs may be inoculated in the yolk-sac, allantoic cavity, amniotic cavity, and on to the chorio-allantois, they may also be inoculated intravenously, intracerebrally, and by other routes.

Fuller technical details than can be given here will be found in the monographs of Stevenson and Butler (1939), and in particular that of Beveridge and Burnet (1946). Of recent years, Burnet has greatly extended our knowledge of the reaction of the chick embryo to viruses and the methods used by most virus workers, if not virtually identical, owe much to his ingenuity. Throughout the following chapter constant reference will be made to methods introduced by Burnet and which are now conveniently collected together in the monograph just referred to

SOME POINTS IN THE EMBRYOLOGY OF THE DEVELOPING CHICK

In order to understand the rationale of the various methods of inoculating eggs, it is essential to be familiar with the fundamental stages in the development of the chick. The following short account is largely taken from the works of de Gadow (1893), Kerr (1919), Lillie (1919), Beveridge and Burnet (1946), confirmed by personal observations with J. H. Fodden

After about 4–5 days of development, the embryo is seen to be surrounded by the amniotic and chorionic membranes, which develop from extra-embryonic sources The embryo is attached to the yolk sac, containing the yolk, by the volk stalk, at this early stage, the yolk sac fills the greater part of the cavity, along with the smaller albumen sac At this period, the allantois can be detected as an outgrowth from the embryo proper, it is essentially formed of entoderm, with an outer mesodermal layer

As development proceeds, the allantois enlarges, and fuses externally with the chorion to form the chorio-allantois. Internally it fuses with the amnion By about the 10th day, the chorio-allantoic membrane should line the inside of the shell closely At this stage the embryo is of fair size, and lies floating in the amnion, which is surrounded externally by the large allantoic cavity separating the amnion from the chorio-allantois

It may be helpful at this point to describe briefly the various portions of the egg that are of importance in virus work, and at the same time discuss the changes that occur on further incubation

The Shell and Shell Membrane

The shell membrane everywhere lines, and is closely adherent to, the shell. The membrane is tough in consistence and has fibers running roughly in the long axis of the egg, but somewhat obliquely. At the broad end of the egg is the air sac, a well-developed space entirely enclosed by shell membrane, the layers of which divide to form the space. The air sac is only of small size in sterile eggs, but becomes of considerable dimensions in fertile eggs.

The Chorio-allantois

The chorio-allantois is a delicate membrane comprised of chorionic ectoderm externally and allantoic entoderm internally. Between the two layers are numerous blood vessels, capillaries, veins, and arteries, embedded in mesoderm. Two main arteries run from the yolk stalk to the chorio-allantois, the venous return is by two veins associated with the arteries, and by the larger independent allantoic vein.

The chorio-allantois is the main respiratory organ of the embryo, it bleeds readily when damaged. The chorio-allantois is adherent to the shell membrane in all areas, but the two can be separated quite readily.

Levaditi and Grabar (1943) have isolated elementary body-like structures, 200–300 mμ in diameter, from normal chorio-allantoic membranes, and these have to be considered when preparing vaccinial and other virus suspensions.

The Allantoic Cavity

This cavity, which contains 6 c.c. or more of fluid, at its maximum development about the 13th day, is lined by allantoic entoderm, by the time of hatching there is hardly any allantoic fluid left. The fluid is fairly clear, until about the 12th day, when it becomes turbid owing to the presence of urates excreted by the kidneys. Bacterially infected allantoic fluid gives a "false positive" agglutination of chick red cells, which is, however, inhibited by normal serum (Florman, 1946).

Important studies on the antigenic properties of particles prepared from normal allantoic fluid have been made in connection with work on influenza virus.

The pH values of allantoic fluids from noninfected eggs show a rapid drop from the 12th–17th day of development, the Eh of fluid from normal eggs also shows a significant relationship to the state of development, most specimens showing a positive potential (Walker, 1943 *b*, Research Staff, 1945). [For information on the specific conductance and surface tension of egg fluids, see Walker, 1943 *a*, *c*.]

The Amniotic Cavity

The amniotic cavity contains only about 1 c.c. of fluid, which is clear until about the 12th day, when the contents of the albumen sac are discharged into the amnion. The presence of this material causes normal amniotic fluid to agglutinate *certain red cells to a titer of not more than 1/32, chick cells are not agglutinated* (Commission, 1946).

The protein content of the amniotic fluid of uninfected 11-day embryos has been calculated as 0.005 per cent (Nagler, 1946).

The Embryo

A macromolecular lipoprotein complex, containing 10.5 per cent ribonucleic acid has been isolated by means of the ultracentrifuge from normal chick embryo tissue. The sedimentation constant and SG indicate a molecular weight of 4,800,000 approximately, and a diameter of 23 mμ (Taylor *et al.*, 1942). The gain in weight and length of the developing embryo can be expressed in the form of an index (Walker, 1938), Walker's Index $= \frac{1{,}000 \sqrt[3]{\text{wet weight in grams}}}{\text{crown-rump length in cm}}$

CHAPTER XIII

THE FERTILE EGG IN THE STUDY OF VIRUSES

The fertile egg had been studied in connection with various problems (see Goodpasture, 1938), before Rous and Murphy in 1911 made use of the developing chick embryo in their study of the Rous sarcoma. Twenty years elapsed, however, before the method was generally introduced into bacteriology by Woodruff and Goodpasture (1931), in their study of fowl-pox virus.

Goodpasture and his collaborators made use of the fertile egg not only in studying virus infections (see below), but also in investigating various problems in bacteriology and serology, in the course of which they showed that the embryo could be inoculated not only on the chorio-allantois but also in the amniotic sac and intravenously. (See Buddingh and Polk, 1937; Gallavan, 1937; Gallavan and Goodpasture, 1937, Polk, Buddingh and Goodpasture, 1938; Buddingh and Polk, 1939, *a*, *b*.)

Eggs may be inoculated in the yolk-sac, allantoic cavity, amniotic cavity, and on to the chorio-allantois; they may also be inoculated intravenously, intracerebrally, and by other routes.

Fuller technical details than can be given here will be found in the monographs of Stevenson and Butler (1939), and in particular that of Beveridge and Burnet (1946) Of recent years, Burnet has greatly extended our knowledge of the reaction of the chick embryo to viruses and the methods used by most virus workers, if not virtually identical, owe much to his ingenuity. Throughout the following chapter constant reference will be made to methods introduced by Burnet and which are now *conveniently collected together in the monograph just referred to.*

SOME POINTS IN THE EMBRYOLOGY OF THE DEVELOPING CHICK

In order to understand the rationale of the various methods of inoculating eggs, it is essential to be familiar with the fundamental stages in the development of the chick The following short account is largely taken from the works of de Gadow (1893), Kerr (1919), Lillie (1919), *Beveridge and Burnet (1946), confirmed by* personal observations with J. H. Fodden

After about 4–5 days of development, the embryo is seen to be surrounded by the amniotic and chorionic membranes, which develop from extra-embryonic sources The embryo is attached to the yolk sac, containing the yolk, by the yolk stalk, at this early stage, the yolk sac fills the greater part of the cavity, along with the smaller albumen sac At this period, the allantois can be detected as an outgrowth from the embryo proper, it is essentially formed of entoderm, with an outer mesodermal layer

As development proceeds, the allantois enlarges, and fuses externally with the chorion to form the chorio-allantois Internally it fuses with the amnion By about the 10th day, the chorio-allantoic membrane should line the inside of the shell closely At this stage the embryo is of fair size, and lies floating in the amnion, which is surrounded externally by the large allantoic cavity separating the amnion from the chorio-allantois

It may be helpful at *this point to describe briefly the various portions of the* egg that are of importance in virus work, and at the same time discuss the changes that occur on further incubation

thin basement membrane can be shown by silver staining. There is a thin submucosal layer of mesenchyme, and then a very narrow layer of smooth muscle fiber.

About the 13th day, clefts appear at regular intervals in the parabronchi, and extend down to the basement membrane; this bulges outward in front of the evaginations from the parabronchial wall. The evaginations grow through and disrupt the muscle cell layer of the parabronchi. The tubular evaginations, or saccules, are lined by a single layer of cuboidal cells. The lumen of the parabronchus communicates directly with the vestibule which leads into the peripheral air capillaries or labyrinth, by the 21st day the labyrinth has completely developed by anastomosis of the air capillaries formed from the earlier evaginations.

The mesenchyme is composed chiefly of undifferentiated stellate cells with a clear cytoplasm and a small, central dark-staining nucleus. The mesenchyme becomes divided into regular hexagonal areas by thin, densely staining endothelial cells linked together to form blood capillaries. Eventually the labyrinth of air

spaces.

Air Sacs

Birds have structures known as air sacs which radiate from the thorax to the abdomen and bones. These organs are not respiratory, but act as "balloons" filled with air. They are derived from the ends of the entobronchi about the 7th day of development, and have the same histological structure, some of the epithelial cells being ciliated

The Albumen Sac

The albumen sac discharges into the amniotic cavity at about the 12th day, through a small communicating duct—the sero-amniotic junction

The Yolk Sac

The yolk, or nutritive fluid, is enclosed in a sheet of vascular, entodermal tissue known as the yolk sac. The interior of the yolk sac is broken up by villous growth, except for a bare area around the yolk stalk The yolk gradually decreases in quantity as development proceeds, and occupies only a small volume at the time of hatching

SOURCE, SUPPLY, AND INCUBATION OF EGGS

Eggs should be obtained from a reliable poultry farm, and delivery should be rate of 80 per cent. should be reached. ion, otherwise they have to be washed

or 3–4 days An egg incubator running at 38°–39° C. is used, but certain workers prefer 37.5°–38° C. for "setting."

Beveridge (1944) has found that embryos incubated at 39° C before inoculation differ from those incubated at 36.6°–37.8° C in the following respects (a) they yield about half the volume of allantoic fluid when infected with influenza; (b) they are not so susceptible to infection with influenza virus injected in the allantoic cavity, (c) chorio-allantoic scarring is more usual He did not find that when influenza virus is injected amniotically or in the yolk sac that the temperature of preliminary incubation has any effect.

The eggs must be turned twice daily, and allowed to cool for 10 minutes on one of these occasions. The tray in the bottom of the egg incubator should be

From the point of view of virus work, interest centers on the histological appearances of the respiratory system up to about the 20th day.

Histology of the respiratory system.

This has been studied by various authors, who give the following account (Gadow, 1893; Juillet, 1911–12; Kerr, 1919; Lillie, 1919; Gallavan and Goodpasture, 1937, Bremer, 1939, Burnet, 1940 *a, b*, Fodden and Rhodes, 1947):

Entodermal diverticula destined to form the lungs grow from the laryngotracheal groove. These diverticula form an elongated air-tube known as the mesobronchus, which extends through all the lung tissue on either side. All the air sacs and passages of the lung develop from the mesobronchus by budding and branching. The buds and branches grow out into primitive mesenchyme.

By the end of the 6th day, several distinct tubular divisions of the mesobronchus are noted, known as secondary bronchi or entobronchi. By the 9th day of development, these in turn divide into innumerable smaller parabronchi which radiate into the rapidly expanding mesenchyme.

By the 11th day, this cellular growth has transformed the lung into an organ composed of epithelial parabronchi embedded in mesenchyme. Developing blood vessels divide the mesenchyme into multiple hexagonal areas, each enclosing a tubular parabronchus.

From the 12th day onward, the parabronchi are the most prominent structures in section They are lined with respiratory epithelium. At about this stage, large numbers of saccular outgrowths develop from the parabronchi.

At this period Burnet (1940 *a, b*) regards the following as constituting a normal appearance (1) a uniform and complete epithelial lining of the parabronchi, (2) the absence of degenerative changes in epithelial cells, apart from some goblet-cell appearances, (3) absence of cells from the parabronchial lumen, (4) the saccules are clearly defined, (5) the mesenchyme is composed of loosely packed uniform cells

The saccules push out into the mesenchyme, and become elongated cul-de-sacs About the 16th day, their ends divide, and continue as narrower tubes which abut onto the surrounding vessels developing in the hexagonal area of mesenchyme. The proximal portion, opening from the lumen of the parabronchus, is known as the vestibule The narrow tubes divide and form a complicated anastomosing labyrinth of fine air capillaries, surrounding the parabronchus, the labyrinth is *developed on about the 20th day There has been considerable* discussion as to whether there is an epithelial lining to the finer air capillaries, and it appears that there is such a layer (Bremer, 1939)

We have with J H. Fodden, studied the histology of the developing respiratory tract, with the object of defining the normal appearances in routine sections, so that pathological changes can be the better understood Our own observations completely confirm and somewhat extend those of Burnet (1940 *a, b*).

During the early days, the mesobronchus is the most prominent structure in sections of lung It extends from the hilum throughout the mesenchyme The mesobronchus is circular, and lined with pseudostratified columnar cells These cells are ciliated, and have a faintly granular cytoplasm with a large pale granular nucleus There is a well-marked basement membrane resting on a narrow reticular submucosa, made up of concentrically arranged spindle-shaped cells, the submucosa contains smooth muscle fibers

About the 7th day, *many entobronchi have been formed by evagination* of the entire wall of the mesobronchus Microscopically the entobronchus resembles the parent mesobronchus, and the epithelial cells are ciliated

The entobronchi, in their turn, give rise to very large numbers of small air tubes or parabronchi These are circular tubes with a broad epithelial lining of tall nonciliated columnar cells, the nuclei of which often show mitoses A complete

thin basement membrane can be shown by silver staining. There is a thin submucosal layer of mesenchyme, and then a very narrow layer of smooth muscle fiber.

About the 13th day, clefts appear at regular intervals in the parabronchi, and extend down to the basement membrane, this bulges outward in front of the evaginations from the parabronchial wall. The evaginations grow through and disrupt the muscle cell layer of the parabronchi The tubular evaginations, or saccules, are lined by a single layer of cuboidal cells The lumen of the parabronchus communicates directly with the vestibule which leads into the peripheral air capillaries or labyrinth, by the 21st day the labyrinth has completely developed by anastomosis of the air capillaries formed from the earlier evaginations

The mesenchyme is composed chiefly of undifferentiated stellate cells with a clear cytoplasm and a small, central dark-staining nucleus. The mesenchyme becomes divided into regular hexagonal areas by thin, densely staining endothelial cells linked together to form blood capillaries. Eventually the labyrinth of air capillaries almost replaces the original mesenchyme of the hexagon From the larger blood vessels fine capillaries penetrate, and are closely applied to, the labyrinth. In the later stages the pulmonary mesenchyme is represented by the sparsely cellular stroma supporting the epithelial structures, pulmonary blood vessels, and lymph spaces.

Air Sacs

Birds have structures known as air sacs which radiate from the thorax to the abdomen and bones. These organs are not respiratory, but act as "balloons" filled with air They are derived from the ends of the entobronchi about the 7th day of development, and have the same histological structure, some of the epithelial cells being ciliated

The Albumen Sac

The albumen sac discharges into the amniotic cavity at about the 12th day, through a small communicating duct—the sero-amniotic junction

The Yolk Sac

The yolk, or nutritive fluid, is enclosed in a sheet of vascular, entodermal tissue known as the yolk sac The interior of the yolk sac is broken up by villous growth, except for a bare area around the yolk stalk The yolk gradually decreases in quantity as development proceeds, and occupies only a small volume at the time of hatching.

SOURCE, SUPPLY, AND INCUBATION OF EGGS

Eggs should be obtained from a reliable poultry farm, and delivery should be [illegible] rate of 80 per cent should be reached.
[illegible] ion, otherwise they have to be washed

[illegible] or 3–4 days. An egg incubator running at 38°–39° C is used, but certain workers prefer 37.5°–38° C. for "setting"

Beveridge (1944) has found that embryos incubated at 39° C before inoculation differ from those incubated at 36.6°–37.8° C in the following respects (a) they yield about half the volume of allantoic fluid when infected with influenza, (b) they are not so susceptible to infection with influenza virus injected in the allantoic cavity, (c) chorio-allantoic scarring is more usual He did not find that when influenza virus is injected amniotically or in the yolk sac that the temperature of preliminary incubation has any effect

The eggs must be turned twice daily, and allowed to cool for 10 minutes on one of these occasions The tray in the bottom of the egg incubator should be

kept filled as directed by the makers In all models of incubator the atmosphere should be kept humid. We have used a gas-heated incubator, and in general have found it most reliable, although an electric one is perhaps preferable.

Hens' eggs are usually used, although ducks' have been employed (Himmelweit, 1938, Beveridge and Burnet, 1946).

"Candling" of Eggs

Eggs are examined by "candling," preferably in a dark room, to see if germination has occurred.

The embryo shows up as a dark area, in contrast to the rest of the egg which is translucent. Movements can usually be detected, and the blood vessels in the chorio-allantois can be readily seen The air sac is clearly visible. Sterile eggs appear translucent. Premature death of the embryo is detected by undue mobility of the shadow and absence of vascular pulsation

Incubation after Inoculation

After inoculation, eggs are incubated in an ordinary bacteriological incubator at 35°–36° C, for 2–4 days, depending on the agent They must not be disturbed during this process. There is evidence that a number of virus agents grows best at this temperature, in preference to 37° C Thus, Sigurdsson (1943) found that embryos incubated at the higher temperature were more resistant to vesicular stomatitis than were those inoculated at 35°–36° C Various similar observations have been made (Beveridge and Burnet, 1946).

INOCULATION OF THE CHORIO-ALLANTOIS

This method was the first to be used in virus work. A number of different methods are available.

Goodpasture's Méthod

This method has been used by Goodpasture and his collaborators (Woodruff and Goodpasture, 1931, Goodpasture, Woodruff, and Buddingh, 1931, 1932, Goodpasture *et al*, 1935, and see Goodpasture, 1938). Twelve-day eggs are candled, and the site of the chorio-allantoic membrane outlined Paraffin is thinly painted on the shell The eggs, resting on plasticine, are then placed in water at 40° C, this reaches up to, but does not touch, the paraffin A window of 1–1½ sq cm is cut in the paraffined surface, using a hard steel trocar (ground with a triangular end and sharp point) The shell is levered off and paraffin painted over the more or less undamaged shell membrane beneath, this is then torn and folded over the cut shell, to expose the chorio-allantois The inoculum is then placed on the chorio-allantois, and a rim of vaseline-paraffin mixture built round the edge of the window, a cover-slip being pressed firmly down on the top Examination of the chorio-allantoic membrane can be carried out through the window from day to day

Burnet's Method

This modification of Goodpasture's method was introduced by Burnet (1933, 1936 *b*), and has been improved from time to time (Beveridge and Burnet, 1946) The air space is first pencilled in, then an equilateral triangle, with 12 mm sides, is marked over the area of densest opacity of the embryo The sides of this triangle are cut through with a rotating disk driven by a dental engine Two intersecting cuts are made over the air sac, which is then pierced with a short, four-sided, sharp steel rod. The triangle of shell already cut is then removed and the shell membrane slit in the direction of its fibers *Slight suction is applied* with a teat to the hole in the air sac In this way the egg contents are displaced and an artificial air space formed between the shell membrane and the chorio-allantois Inoculation of 0 05 c c of material is then made with a sterile Pasteur pipette. The orifice is rimmed and

sealed as in Goodpasture's method, while the air sac hole need not be sealed The egg must be most carefully handled in all subsequent manipulations It is useful to place a small amount of sterile saline on the shell membrane before it is punctured On puncturing, the saline will "seep" in and separate the chorio-allantois from the shell membrane. This process is intensified when suction is applied to the air sac (Burnet and Faris, 1942). Beveridge (1947) describes a technique obviating the use of a drill.

For sealing the egg, cellophane triangles (boiled in distilled water) dipped in sterile egg albumen can be recommended. Adhesive tape is also useful. A somewhat similar method to this has been used by Bengtson and Dyer (1935). These workers cut only two sides of the triangle, bending back the flap to break the third side. Injections are made through the vaseline after the orifice is covered

Stevenson and Butler's (1939) Method

The air chamber and a small circle 1 cm. in diameter on the side of the egg (within the opaque area) are pencilled in. The egg is then placed on plasticine with the inoculation site laterally, the shell over this area is swabbed with rectified spirit and flamed If the air sac is to be pierced, the shell over this area also should be sterilized. Using a sterile scalpel a hole is then drilled through the shell of the inoculation site When the hole is made one should look for the pink chorio-allantoic vessels or slight bleeding, if neither is noted, discard the egg.

The actual inoculation is now carried out by one of the three following methods (*a*) The inoculum is introduced through the hole with a capillary pipette, very little, if any, pressure being applied to the teat. (*b*) First blow in a puff of air, then the inoculum (using separate pipettes). (*c*) After the lateral opening has been made, the air sac is punctured, air is then blown into the lateral hole and finally the inoculum All holes are sealed with paraffin or cellulose acetate in ether or acetone

Another Method

The following method has been recommended (Alexander, 1938, Dunham, 1942, Beveridge and Burnet) An oval opening about 2 × 3 mm. is made by removing the shell with a side-to-side movement of a rotating disc. The area immediately surrounding is brushed with sterile melted paraffin wax The shell membrane is clarified by the smallest possible drop of liquid paraffin. The inoculum is then deposited on the shell membrane, which is punctured through the drop Suction is then applied to the air sac, and the inoculum drawn in The hole is sealed with melted paraffin We have used this method with successful results

Opening and Examination of Eggs

Even with the best technique, some 10 per cent of embryos will die apart from the specific effect of the inoculation After 3 to 4 days, the eggs are ready for examination, the actual time depends on the virus used The eggs should be opened resting on cotton wool soaked in antiseptic, standing in a Petri dish. In Goodpasture's and in Burnet's methods the vaseline and coverslip are removed, and the eggshell broken away with sterile forceps until enough access has been obtained The membrane can be dissected out *in situ* with sterile curved nail scissors In Stevenson and Butler's method the procedure is as follows The egg is rubbed over with rectified spirit from the narrow end to the middle. The narrow end is then dipped into rectified spirit down to one third of the egg The egg is then placed in a metal holder and flamed The sterile (narrow) end projects beyond the holder, and is cracked with a heavy instrument. The shell is picked off the shell membrane with forceps The exposed portion of the shell membrane is then peeled off with another pair of forceps, and the chorio-allantois exposed, with a third pair of

forceps this structure is torn across. The egg is tilted and the contents delivered, the chorio-allantois remains in the shell and is removed into a sterile Petri dish.

Aerobic and anaerobic cultures should be made from every egg opened, if the contents are to be studied further

The membrane removed from the shell is pinned out on a board against a dark background. After fixing in formalin or Zenker's solution, the pocks or other lesions may be counted and examined with a lens or plate-culture microscope. If it is desired to examine paraffin sections of the infected membrane, dehydration and embedding can thereafter be carried out, the membrane being rolled into a compact mass. Sections can be stained by HE and by special methods for inclusions (Buddingh, 1936).

Another histological method is that of Goodpasture, Woodruff, and Buddingh (1931, 1932): Fix in Zenker's solution for 24 hours. Stain the membrane in 2 per cent aqueous acid fuchsin for 10 to 30 minutes; wash. Counterstain with Löffler's methylene blue for 30 seconds. Differentiate in absolute alcohol, clear, and mount in cedar oil. To preserve membranes entire, these may be taken through alcohol, and mounted in plastic solution (Dunham, 1941).

Pathological Changes

Injections of nonirritating fluids should not cause any more than a slight opacity of the chorio-allantoic membrane, but Burnet (1936 *b*) has described the occasional presence of a traumatic lesion, which is more apt to be found in younger than older

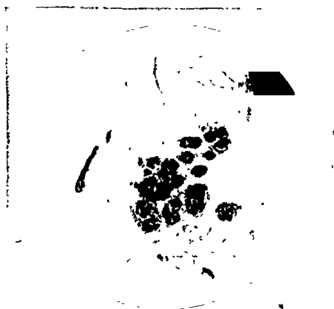

Fig 24 Vaccinial lesions on the chorio-allantois 5 days after inoculation with vaccinia virus, observe the plaques

eggs. It appears as an irregularly thickened opaque area up to 1 cm in length with, microscopically, replacement of ectoderm by granulation tissue, and epithelial downgrowth marginally Nonspecific ulceration is commoner if abrasives are used to prepare inocula.

Goldsworthy and Moppett (1935) found eosinophilic intracytoplasmic and intranuclear bodies in the chorio-allantois unaffected by any virus. D'Aunoy and

Evans (1937) have also drawn attention to the fact that many changes reported in the literature as being specific for viruses can, in fact, be seen in normal eggs Thus they found the following changes to be perfectly normal mesodermal edema and cellular proliferation; endodermal proliferation with vacuolation of cells, which often contained large eosinophilic bodies, probably red cells or degenerated debris; eosinophilic intranuclear bodies were also found

The lesions produced in the egg by genuine viruses, however, are very characteristic, and should not be confused with the appearances just mentioned. Virus dropped on to the chorio-allantois must, unless it be rapidly destroyed, first penetrate the ectodermal layer, here the infection spreads outward with resultant proliferation of infected cells, thereafter, the lesions may assume three main types (Burnet, 1936 *b*)

1. Proliferation of ectodermal cells outstrips the spreading infection, so that a thickened and cornified ectodermal zone surrounds an infected and necrotic center. Burnet states that this type of change occurs with the viruses of ectromelia (incubated at 38° to 39° C.), herpes, influenza, louping-ill, and psittacosis. To the naked eye this change is evident as white areas of dense opacity.

2. In this type the lesion is more destructive, much necrosis occurs, with the [illegible] This type [illegible] is laryngo- [illegible]

3. The ectoderm does not undergo early necrosis, but proliferation spreads out peripherally, and is followed by infection A flat conical lesion of semitransparent appearance, and without central necrosis, results, fowl-pox produces lesions of this type.

In the milder infections the embryo may not be killed, but in the severer types it is destroyed. Virus dropped on the chorio-allantois spreads locally, and may also invade the blood stream, eventually affecting other organs (Anderson, 1940).

Hoffstadt and Tripi (1946) calculated Walker's index (see above) for embryos inoculated with Levaditi's strain of vaccinia. Infected embryos failed to gain as quickly as normals.

Applications of the Chorio-Allantoic Technique

The study of virus morphology.

Numerous workers have found the chorio-allantois a suitable site in which to study the development of inclusion bodies However, in view of the above-mentioned findings of inclusion-like bodies in normal membranes, it would appear as if some, at least, of the bodies described were nonspecific in character. Inclusion bodies characteristic of the following human diseases have been found in stained preparations of [illegible] sittacosis, vaccinia. A [illegible] ectromelia, equine [illegible] laryngotracheitis of [illegible] parrot disease

Himmelweit (1938) has used an ingenious method for studying the formation of virus inclusions *in situ*, working with the duck's egg infected with ectromelia and vaccinia. Briefly, the egg shell was partly cut away and replaced by a coverslip, so that the membrane was visible Microscopic examination was then carried out with a Heine Ultropak (Leitz), which makes use of the principle of annular oblique incidence illumination.

Grafts of human skin, amnion or chorion, already infected with virus, can be placed on the chorio-allantois and the development of inclusions studied by histolog[illegible] 1938) This has been carri[illegible] herpes simplex, variola, and [illegible]

forceps this structure is torn across. The egg is tilted and the contents delivered; the chorio-allantois remains in the shell and is removed into a sterile Petri dish.

Aerobic and anaerobic cultures should be made from every egg opened, if the contents are to be studied further.

The membrane removed from the shell is pinned out on a board against a dark background. After fixing in formalin or Zenker's solution, the pocks or other lesions may be counted and examined with a lens or plate-culture microscope. If it is desired to examine paraffin sections of the infected membrane, dehydration and embedding can thereafter be carried out, the membrane being rolled into a compact mass Sections can be stained by HE and by special methods for inclusions (Buddingh, 1936).

Another histological method is that of Goodpasture, Woodruff, and Buddingh (1931, 1932): Fix in Zenker's solution for 24 hours. Stain the membrane in 2 per cent. aqueous acid fuchsin for 10 to 30 minutes, wash Counterstain with Löffler's methylene blue for 30 seconds Differentiate in absolute alcohol, clear, and mount in cedar oil. To preserve membranes entire, these may be taken through alcohol, and mounted in plastic solution (Dunham, 1941).

Pathological Changes

Injections of nonirritating fluids should not cause any more than a slight opacity of the chorio-allantoic membrane, but Burnet (1936 *b*) has described the occasional presence of a traumatic lesion, which is more apt to be found in younger than older

FIG 24. Vaccinial lesions on the chorio-allantois 5 days after inoculation with vaccinia virus, observe the plaques

eggs. It appears as an irregularly thickened opaque area up to 1 cm. in length with, microscopically, replacement of ectoderm by granulation tissue, and epithelial downgrowth marginally. Nonspecific ulceration is commoner if abrasives are used to prepare inocula.

Goldsworthy and Moppett (1935) found eosinophilic intracytoplasmic and intranuclear bodies in the chorio-allantois unaffected by any virus. D'Aunoy and

The chorio-allantois may be used to test the distribution of virus in experimental animals after various routes of inoculation (Burnet and Lush, 1938).

Titration of antiviral sera.

Eggs may be used in lieu of experimental animals to test the virus-inactivating properties of immune sera. Thus Burnet and Galloway (1934), working with vesicular stomatitis, mixed equal parts of immune serum with falling dilutions of a collodion membrane filtrate of virus. After incubation at 15° to 20° C. for 30 minutes, eggs were injected The usual lethal action of this virus on the embryo was prevented in adequately neutralized specimens. The test proved more sensitive to the presence of unneutralized virus than did a parallel series of injections in the guinea-pig's pad.

When dealing with viruses which produce local pocks on the chorio-allantois, the antiviral properties of immune sera can be tested by their power of diminishing, or actually preventing these lesions. Thus, Keogh (1936) found that antivaccinial sera could be titrated by the percentage reduction effected in the numbers of typical vaccinial pocks, a reduction of 90 per cent. being usually obtained. Burnet (1936 *b*) records a routine method for testing fowl sera for their content of laryngotracheitis antibodies the sera to be tested are mixed with an equal volume of virus (usually diluted 1/10,000), and 1 hour later eggs are injected. Potent sera may completely inhibit the development of the usual lesions.

For the preparation of vaccine for human use.

Egg-cultured virus has been used for human vaccination (see p 382). Goodpasture *et al.*, (1935), for example, giving the following instructions

(*a*) The egg membrane may originally be inoculated with either ordinary lymph, testicular virus, dermal lapine, or directly from the human vaccinial pustule.

(*b*) For the first 3 to 4 passages an incubation period of at least 72 hours is required, although after this period it may be reduced to 48 hours.

(*c*) At least six eggs should be inoculated at each subculture.

(*d*) When the membrane is removed from the egg, a small piece from the center of the lesion should be excised and smears stained for elementary bodies

(*e*) Approximately one-quarter of the lesion is inoculated into dextrose infusion broth and culture carried out. The remainder is placed in the refrigerator to freeze

(*f*) For initiating the next subculture, lesions should be used which show the largest number of Paschen bodies.

(*g*) To maintain the potency of "seed" virus, do not use inocula which have been stored for a considerable period.

(*h*) When titrated, culture virus diluted 1/1,000 should produce a confluent eruption on 90 to 100 per cent of the inoculated area in every test.

(*i*) To prepare vaccine for human inoculation, four parts by volume of 50 per cent. sterile glycerol in saline are added to one part of pulp, pulp is prepared by grinding frozen membrane till finely divided.

Stevenson and Butler (1939) have carried out extensive experiments on the preparation of egg virus

(*a*) Operating inside a special box, vaccinial plaques are removed from the membranes with sterile scissors, after 4 days' incubation.

(*b*) Five to ten plaques may be collected in one dish, weighed, and frozen in the cold room overnight

Grafts of fowl skin have been infected with fowl-pox virus and grafted on the chorio-allantois; after suitable growth, histological material is prepared (Goodpasture and Anderson, 1940). It was found that the epithelium of chickens actively immunized against the virus was resistant while a part of the immunized bird, but became susceptible when grafted on the chorio-allantois.

Cultivation of viruses.

A large number of viruses can be propagated by serial passage through eggs Generally speaking, subculturing is carried out by grinding an infected membrane, and after centrifugation, injecting the supernatant fluid into a fresh egg. Animal or other titrations are usually carried out to prove that there is an actual increase in the virus content of the membrane

Numerous human viruses have been propagated on the chorio-allantois, and the references will be found in the appropriate chapters.

Numerous animal viruses have also been grown.

Titration of viruses.

Virus titrations can be carried out on the chorio-allantois; death of the embryo may be used as the end-point, or the number of pocks may be counted, according to the virulence of the particular strain of virus For any given strain, the relation between the number of virus particles inoculated and the number of pocks produced will be essentially constant; the more virulent the strain in the embryo, the closer to unity is the relation (Beveridge and Burnet, 1946).

Burnet and Ferry (1934), in their studies on fowl-plague and Newcastle disease, inoculated eggs with varying dilutions of virus, and found that infective doses produced death of the embryo within 48 hours. The method whereby the potency of the virus is estimated by counting the number of pocks produced on the chorio-allantois has been carried out for a number of viruses· vaccinia, by Keogh (1936), ectromelia, by Burnet and Lush (1936 *a*); Kikuth's canary virus and fowl-pox, by Burnet and Lush (1936 *b*), and infectious laryngotracheitis by Burnet (1936 *a*) As an illustrative example of the methods used in this class of work, the study of Keogh (1936) on vaccinia may be cited Eggs incubated for 12 days were inoculated with virus, and pock counts made after 48 hours. An initial series of experiments was carried out to determine the approximate strength of virus giving discrete pocks Thereafter, falling dilutions of 3 were prepared, starting at 1/300 and continuing down to 1/24,300, the bulk of inoculum being 0 05 c c. The 1/300 dilution was found to give too many pocks to count accurately, and the pocks in the 1/900 dilution were also somewhat confluent, the 1/24,300 dilution gave an average of 7 5 pocks, the 1/2,700 and 1/8,100 dilutions giving figures of 61 and 21 pocks It was found by a parallel series of intradermal titrations in rabbits that the titers obtained by this method corresponded closely with those by the pock-counting method

Burnet and Faris (1942) found that with vaccinia, the general nature of the relationship was such as to give a series of the type 1–10–62–300 foci for successive tenfold dilutions, with influenza (WS) egg-adapted virus, on the other hand, the relationship was linear

To experienced workers, there is no significant subjective influence in pock counts, with well-defined pocks, the use of 4–6 membranes gives results accurate to ± 50 per cent (Beveridge and Burnet, 1946).

Rabbit myxoma virus can also be titrated on the membrane, and we have worked with fowl-pox with Reed and Crawley in these laboratories

Isolation of viruses.

It has been claimed that influenza virus may be isolated by direct inoculation of eggs with nasopharyngeal secretion (see p 616) Variola can be isolated by these methods (see p 346)

forceps is used to peel off the shell membrane covering the "floor" of the air sac, thus exposing the chorio-allantois, and the underlying allantoic cavity filled with fluid. A small hole is made in the chorio-allantois, avoiding blood vessels The fluid is aspirated with a Pasteur or other type of sterile pipette fitted with a rubber teat. The point of the pipette is passed toward the side of the egg to avoid blockage.

Applications

Allantoic inoculation is widely used in work with influenza virus, Newcastle disease virus will also grow in this cavity, as will certain other viruses

The main applications of the technique are as follows· (1) Passage of laboratory strains (2) Primary isolation from human material (3) To yield a source of crude virus that can be purified for morphological, chemical, and serological studies, and for use as a vaccine. (4) As a source of antigen in serological tests. (5) As a means of titrating virus suspensions or estimating the virus-neutralizing properties of antisera. (6) In chemotherapeutic experiments.

AMNIOTIC INOCULATION

Goodpasture and his collaborators first showed that inoculations could be made into the amniotic sac, by direct vision (Gallavan and Goodpasture, 1937, Buddingh and Polk, 1939 *a*, *b*).

The inoculation of viruses into the amniotic cavity was introduced by Anderson (1940), and Burnet (1940 *a*, *b*, Burnet and Foley, 1941 *a*, Beveridge and Burnet, 1946), and has been widely used, particularly in work with influenza virus. By injecting trypan blue into the amniotic cavity, Burnet (1940 *b*) showed that it was swallowed and passed through the alimentary canal, the mouth and trachea were stained. The object of amniotic inoculation is to introduce material so that it comes in contact with the respiratory tract. Eggs of 13–14 days are usually employed, but for some virus strains younger eggs may be preferred.

Goodpasture's Method

The type of approach is that used for chorio-allantoic inoculation by Goodpasture's method, without any dropping of the membrane. The inoculation is made through the chorio-allantois and amnion into the amniotic cavity with a narrow needle (Gallavan and Goodpasture, 1937, Buddingh and Polk, 1939 *a*, *b*) Anderson (1940) used this method to study the pathological changes produced by herpes

Burnet's Method

Thirteen-14 day eggs are used, and the position of the densest area of the embryo is marked on the shell An oval area 2 × 1 5 cm is drilled over this spot, two further cuts are made running across the oval to make a roughly diamond-shaped area at the air sac end of the oval A hole is then drilled in the air sac, and the diamond-shaped area of shell removed A small slit is made in the shell membrane, a drop of sterile saline may be placed thereon, but is not necessary. Suction is applied with a teat to the hole in the air sac, thus causing the chorio-allantois to drop. The remainder of the drilled oval area is now removed and the exposed shell membrane clipped away The chorio-allantois over the embryo is picked up with a fine forceps (held in the left hand) and a small opening is made with scissors The forceps is now used to pick up the amniotic membrane lying immediately under the opening in the chorio-allantois The amnion is gently pulled through the hole in the chorio-allantois, forming a cone. A Pasteur pipette with a fine point, containing 0 05 c c of inoculum and 0 1 c c. of air is then pushed through the base of the cone, and a little air injected to see if a bubble forms under the amnion If so, the correct cavity has been entered and the inoculation is made The amnion is then allowed to slide back The hole in the shell is sealed

(c) The dish is brought to the laboratory surrounded by freezing mixture. The plaques are ground in a mortar, or a special apparatus, to a pulpy consistence.

(d) To prepare vaccine, add 4 c.c. of 50 per cent. neutralized glycerol in distilled water to each 1 gm. of pulp. Store in sterile ampules, screw-topped bottles, or capillary tubes; perform sterility tests.

(e) Vaccine may safely be stored for 6 to 7 months.

Other applications in the study of virus immunity.

(a) *The theory of the antigen-antibody reaction.* Burnet, Keogh, and Lush (1937) have shown that the egg membrane can be used to furnish evidence on the theoretical problem of the antigen-antibody reaction. They have used pock counting and virus neutralization tests with influenza, louping-ill, vaccinia, and other viruses, and have obtained useful information.

(b) *As a source of antigen.* Infected egg membrane has been used as a source of antigen for the complement fixation reaction in influenza.

(c) *In chemotherapeutic experiments.* The fertile egg can be used for the *in vivo* testing of chemotherapeutic agents in viral (and bacterial) infections (Francis, 1946).

ALLANTOIC INOCULATION

The entodermal lining of the allantoic cavity is very susceptible to certain viruses, influenza in particular, and the method of allantoic inoculation is widely used.

Burnet's Method (1941)

Nine-11 day eggs are candled, the air sac pencilled, and a point marked on the shell where the chorio-allantois is well developed, but relatively avascular. A small groove is then made in the shell with the dental drill, and the inoculation of 0·05–0·2 c.c made with a tuberculin syringe and fine needle. The needle is passed through the shell membrane for a depth of 3 mm., thus penetrating the chorio-allantois and entering the allantoic cavity. The small groove is sealed with paraffin-vaseline mixture.

Eggs are incubated at 35°–36° C. for 2 or more days and then opened as described below. *The eggs should be incubated in egg cups or racks with the air* sac end uppermost

Sometimes leakage may occur unless an additional hole is made in the air sac to allow for expansion. Alternatively, the inoculation can be made through the air sac when the drill hole will be sufficient to allow of expansion.

Another Method

Drill a groove in the shell, as above. Brush an area around the groove about 1 cm square with melted paraffin wax. Expel part of the inoculum of 0·05 c.c. over *the groove Thrust a sterile dissecting needle through the drop, through the shell* and chorio-allantoic membranes, into the allantoic cavity When the needle is withdrawn, the fluid will flow in Then add the remainder of the inoculum which will also be aspirated Sealing is accomplished by a drop of molten paraffin (Burnet and Beveridge, 1946)

Opening of Eggs

At the completion of incubation, the eggs are placed in the ice chest for 4–18 hours, to kill the embryo and prevent bleeding The shell in the region of the air sac is sponged with methylated spirit, and the shell drilled through. The top of the egg is then removed with a sharp scalpel or razor blade. A pair of small sterile

Changes Produced in the Embryo

Severe changes are produced in the respiratory tract by influenza virus (see Ch. LIX) and the virus of Newcastle disease of fowls (see Ch LIII)

Herpes virus produces nuclear inclusions in the tissues of the amnion and the skin of the embryo Proliferation and subsequent vesiculation of the cutaneous and pharyngeal epithelium may be noted Invasion of the blood stream may occur (Anderson, 1940). Mumps virus also grows [illegible] multiply and pro- d[illegible]. Laryngotracheitis [illegible] which present the features of epithelial proliferation, formation of intranuclear inclusions, and degeneration without gross necrosis. Psittacosis multiplies freely but produces relatively slight changes, almost confined to the superficial epithelial cells of the larger bronchi

Applications

Amniotic inoculation is extensively used in the study of influenza virus Its main applications are as follows (1) Passage of laboratory strains (2) Primary isolation from washings (3) Titration of virus suspensions

YOLK SAC INOCULATION

Cox's Method

The method of yolk sac inoculation has been chiefly popularized by the work of Cox (1938 *a*, *b*, *c*, 1941).

Eggs are incubated for 5–6 days. They are inoculated in the yolk by passing a narrow gauge needle 1–1½" long into the center of the egg through a groove drilled in the shell of the air sac The inoculum can be up to 0 5 c c. or even 1 0 c c in bulk

Incubation is then carried out at 35°–36° C. Virulent agents invade the embryo and may cause death The yolk sac is removed by drilling away the air sac, and removing the shell membrane and chorio-allantois in its floor. The contents are then gently decanted into a sterile Petri dish If desired, the embryo can first be pulled out and the yolk sac then delivered by traction on the umbilical stalk (Beveridge and Burnet, 1946).

Passage is usually carried out with a 10 per cent. suspension of ground yolk sac tissue, or with yolk itself.

Application

A number of viruses grows readily in the yolk sac, and form characteristic elementary bodies that can be readily detected in smears made of the lining membrane e g , psittacosis, LGI, and pneumonitis viruses.

Typhus rickettsiae grow well in the yolk sac

Yolk sac material is used as a source of vaccine, and as antigen for serological tests in psittacosis, LGI, pneumonitis, and rickettsial infections

Yolk sac inoculation is also of value in the primary isolation of agents of the psittacosis-LGI group

The method can be used to study the effect of drugs and antibiotics on viruses, such as those of the LGI-pneumonitis group An effect of the drug is shown by a delay in the death of the embryo (Hamre and Rake, 1947)

INTRAVENOUS INOCULATION

Embryos can be inoculated intravenously (Polk, Buddingh, and Goodpasture, 1938, Buddingh and Polk, 1939 *a*, Burnet and Beveridge, 1946) The inoculation

with a coverslip resting on a wall of paraffin-vaseline Incubation is carried out at 35° C. for 2–4 days.

In opening the egg after incubation, the shell is chipped away, and the shell membrane cut away, to the margin of [illegible] fluid may be removed if required, and [illegible] egg. Some amniotic fluid is removed w[illegible]

In influenza work, the embryo is then removed to a sterile Petri dish, and the contents of the trachea aspirated with a suitably drawn-out and slightly bent Pasteur pipette In infected embryos the fluid is turbid, normally it is clear. The fluid is centrifuged in a capillary, and a Leishman-stained film made from the deposit.

The trachea and lungs can then be dissected out for histological examination We ourselves prefer to fix the embryo entire for such an examination.

If passage or titration experiments are to be carried out, the lungs are removed with sterile precautions and ground with powdered abrasive in 1 c.c. of broth. Passage can also be performed with ground tracheas.

Burnet and Beveridge (1946) have described an improved method of locating the embryo. The egg is candled and the site of the main allantoic vein pencilled. This vein can be seen near the air sac, or its position inferred from the convergence of two large veins. The egg is held with the air sac end towards the operator, and a line is traced back from the allantoic vein to the broadest diameter of the egg. The inoculation site lies on this diameter, but ½″ away from the line in a clockwise direction.

We use a simplified method based on that of Goodpasture and Burnet (Rhodes, 1946). The egg is candled, and an equilateral triangle marked overlying the embryo. The triangle is drilled and then removed A small drop of sterile saline is placed on the exposed shell membrane, which is then punctured. The saline helps to separate the chorio-allantois. The shell membrane is clipped away to expose the chorio-allantois. This is incised by a touch of a hot needle, which acts as a hemostatic. The amnion is pulled through this hole with a delicate pair of forceps held in the left hand. The inoculation is then made with a syringe and fine needle held in the right hand This method obviates the necessity for "dropping" the chorio-allantois

Hirst's (1942) Method

In this method, the inoculation is performed over an egg candler. The egg is rotated till the shadow appears near the upper surface One puncture is then made in the shell of the air sac and another overlying the embryo. The inoculation is made through the latter hole with a 22 gauge, 1″ long needle, thrust quickly in, nearly to full length. If the embryo is hit, the shadow disappears, but can be made to reappear by moving the needle The inoculum is 0 2 c c.

By this method, some of the inoculum, if not all, presumably goes into the tissues of the embryo, rather than directly into the amniotic cavity.

Taylor and Chialvo's (1942) Method

Remove the shell and shell membrane overlying the air sac and expose the floor Render the floor translucent with a few drops of spirit, so that the border of the underlying yolk sac and blood vessels can be noted. Avoiding these structures, plunge the points of a pair of fine forceps through the two membranes and fairly deep down Open the points to grasp the amnion and withdraw a small "tent" through the hole Inoculate into the base of the exposed amniotic fold and let it fall back into place Cover the air sac with a suitably shaped glass cup Incubate in an upright position. To examine the embryo, remove the cup, cut away the shell membrane and chorio-allantois, lift out the embryo with forceps, and place in a Petri dish Allantoic fluid may first be aspirated

and this prop-
to egg yolk
10-day em-
bryos is less anaphylactogenic than that from other embryos (Berge and Hargett). Formalin reduces somewhat the danger of allergic reactions (Randall, Mills, and Engel, 1947).

4. Sensitivity to chick and egg antigens in human beings may follow inoculation with whole embryo vaccines (Stull), these vaccines contain egg yolk, yolk sac, and chick embryo antigens, but very little egg white.

5 Using the Prausnitz-Kustner passive transfer technique, Stull found that typhus vaccine gave positive skin reactions in high dilution

6. Highly purified rickettsial bodies do not appear to contain significant amounts of egg antigens.

7. Ideally, a skin test with egg and chick antigens should be performed before *inoculating persons with egg vaccines. The vaccines known to contain egg and* chick antigens should be avoided in persons giving a history of susceptibility to egg or chick. In an important study, Rattner and Untracht (1946) review a number of instances where serious and even fatal allergic manifestations have followed the administration of egg vaccines to sensitive persons. In a group of allergic children, they found that the intradermal inoculation of 0·02 c c of allantoic fluid vaccine served to identify the dangerously sensitive persons In those giving a severe reaction to the skin test, adrenalin should be given along with the dose of vaccine; where the skin reaction is very extensive, the vaccine should not be given at all.

can often be made in a large vein crossing the floor of the air sac, after removal of the shell, if the shell membrane is clarified with a drop of sterile liquid paraffin Alternatively, a large vein can be located in the superficial chorio-allantois by candling. The direction of flow of blood is ascertained if possible. The shell overlying this area is removed, and a drop of liquid paraffin applied to clarify. A 27-gauge needle is then inserted acutely, in the direction of flow; the needle should rest on the shell.

To obtain blood after intravenous inoculation, the needle can be inserted in the opposite direction. Alternatively, a large vessel under the floor of the air sac can be nicked, when the blood will collect on the shell membrane. If desired, the embryo can be dissected and heart blood aspirated.

INOCULATION BY OTHER ROUTES

1. *Intracerebral inoculation* can be performed (Buddingh and Polk, 1939 *a*, Anderson, 1940, Dawson, 1941). The essential of this method is accurate location of the head by candling. A window or triangle is cut in the usual way, and 0 05 c.c. inoculated into the brain with a 27-gauge needle inserted with a sharp jab. Anderson (1940) fou
tion of herpes virus,
even from there alo
Dawson found Negri bodies.

2. *Intra-ocular inoculation* can also be carried out (Dawson, 1941).

3. *The albumen sac* can be inoculated (Polk, Buddingh, and Goodpasture, 1938).

4 *The tissues of the embryo* can be inoculated, either by the usual type of ap-
...ed into the embryonic tissues
...needle into the center of the
1937, Polk, Buddingh, and Goodpasture, 1938, Buddingh and Polk, 1939 *a*) An intraperitoneal injection can be given by pulling out a leg and passing the needle through the thigh (Polk, Buddingh, and Goodpasture, 1938). Anderson (1940) infected embryos with herpes by scarification, and by subcutaneous inoculation, producing characteristic histological changes locally. Peritonitis, and ascending myelitis might occur as the result of the spread of the virus.

Vaccines can be prepared from minced whole chick embryo tissue and are used in yellow fever, and equine encephalomyelitis.

In large scale vaccine production it is useful to use mechanical aids for opening and removal of embryos such as described by Pickels (1942), so that a thousand eggs or more can be handled in an hour.

EGG VACCINES

Vaccines prepared from the egg are being increasingly used, the best known are influenza vaccine from allantoic fluid, typhus and spotted fever vaccines from yolk sac, and encephalomyelitis and yellow fever vaccines from whole embryo

Egg vaccines possess many advantages, and in particular the risk of contamination with bacteria or latent viruses in animal tissues is greatly minimized It is important to realize, however, that these ... sensitize guinea-pigs and human beings to ...ckoff, and Bohnel, 1941, Berge and Hargett, 1... 1946, Stull, 1946) The more important observations are as follows

1. It is rare for normal uninoculated adults to give a skin reaction to typhus (yolk sac) vaccine, egg white, or egg yolk (Plotz)

2 A course of yolk sac vaccine can induce skin sensitivity to egg antigens (Plotz).

SECTION 2. DISEASES OF THE SKIN AND MUCOUS MEMBRANES

CHAPTER XIV

MOLLUSCUM CONTAGIOSUM

BATEMAN (1817) of London has been credited with being the first physician to recognize the disease clinically. Paterson (1841), on the other hand, suggested that the disease was probably noticed earlier, about 1793, by Tilesius Bateman (1817) made a reference to the latter, but called Tilesius's case one of molluscum pendulum Bateman's illustration showing a case of molluscum contagiosum affecting the face of a young woman is typical of the condition, but it appears to be different from his picture showing molluscum pendulum, and so in all probability the two diseases may have been dissimilar.

CLINICAL AND PATHOLOGICAL FEATURES

Molluscum contagiosum usually commences as a pimple in the skin which becomes red, tender, and swollen, and gradually develops into a small yellowish-pink tumor varying in size from a pin-head to a hazel nut. The skin over its surface is tightly stretched and shiny, and usually presents a central dimple. Such lesions are liable to appear on any part of the skin—the face, arms, buttocks, back, and sides being probably the commonest sites for their occurrence, less commonly the genitalia, margins of the eyelids, or scalp become involved The tongue and mucous membrane of the mouth are seldom affected, and the soles of the feet and hands are said never to be attacked The molluscum tumor frequently undergoes suppuration, and scratching of the area may spread the disease to healthy parts of the body.

Molluscum of the eyelids may be complicated by a secondary conjunctivitis and keratitis, microscopical sections show the presence of typical inclusion bodies (von Papolczy, 1933, Quill, 1940, Magnus, 1944).

Inoculation of filtered or unfiltered molluscum tissue extracts into the skin of human volunteers produces lesions after a long incubation, stated by Juliusberg (1905) to be 50 days, by Wile and Kingery (1919) to be 14 to 25 days, and by Findlay (1930) to be 35 days

Molluscum is more common in children than adults. A section made through the center of a nodule shows a down-growth of superficial epithelium extending into the deeper layers of the skin The cells are grouped into little bundles, and the center of the collection is occupied by a mass of hyaline degenerated epithelial cells Each of these cells is enlarged to three or four times its normal size, the nucleus being pushed to one side, and the cytoplasm occupied by a comparatively large hyaline oval mass, the Henderson-Paterson (1841) or molluscum inclusion body

EPIDEMIOLOGY

Geographical distribution The condition has been recognized by clinicians in different parts of the globe, and since its original description in England cases have been reported from countries as widely separated as Germany, India, France, Holland, Spain, the United States of America, French West Africa, the Belgian Congo,

SECTION 2. DISEASES OF THE SKIN AND MUCOUS MEMBRANES

CHAPTER XIV

MOLLUSCUM CONTAGIOSUM

BATEMAN (1817) of London has been credited with being the first physician to recognize the disease clinically Paterson (1841), on the other hand, suggested that the disease was probably noticed earlier, about 1793, by Tilesius Bateman (1817) made a reference to the latter, but called Tilesius's case one of molluscum pendulum Bateman's illustration showing a case of molluscum contagiosum affecting the face of a young woman is typical of the condition, but it appears to be different from his picture showing molluscum pendulum, and so in all probability the two diseases may have been dissimilar.

CLINICAL AND PATHOLOGICAL FEATURES

Molluscum contagiosum usually commences as a pimple in the skin which becomes red, tender, and swollen, and gradually develops into a small yellowish-pink tumor varying in size from a pin-head to a hazel nut The skin over its surface is tightly stretched and shiny, and usually presents a central dimple. Such lesions are liable to appear on any part of the skin—the face, arms, buttocks, back, and sides being probably the commonest sites for their occurrence; less commonly the genitalia, margins of the eyelids, or scalp become involved The tongue and mucous membrane of the mouth are seldom affected, and the soles of the feet and hands are said never to be attacked The molluscum tumor frequently undergoes suppuration, and scratching of the area may spread the disease to healthy parts of the body.

Molluscum of the eyelids may be complicated by a secondary conjunctivitis and keratitis, microscopical sections show the presence of typical inclusion bodies (von Papolczy, 1933, Quill, 1940, Magnus, 1944).

Inoculation of filtered or unfiltered molluscum tissue extracts into the skin of human volunteers produces lesions after a long incubation, stated by Juliusberg (1905) to be 50 days, by Wile and Kingery (1919) to be 14 to 25 days, and by Findlay (1930) to be 35 days

Molluscum is more common in children than adults. A section made through the center of a nodule shows a down-growth of superficial epithelium extending into the deeper layers of the skin The cells are grouped into little bundles, and the center of the collection is occupied by a mass of hyaline degenerated epithelial cells Each of these cells is enlarged to three or four times its normal size, the nucleus being pushed to one side, and the cytoplasm occupied by a comparatively large hyaline oval mass, the Henderson-Paterson (1841) or molluscum inclusion body.

EPIDEMIOLOGY

Geographical distribution The condition has been recognized by clinicians in different parts of the globe [illegible]
been reported from co
land, Spain, the Unitec

the Philippines, and Italy. Therefore, under present-day conditions of travel, the disease can be assumed to possess a world-wide distribution (see von Prowazek, *1911*, *Spillman et al.*, *1930*, *Chiyuto*, *1932*; *Ghosh*, *1934*, *Rossi*, *1935*; van den Berghe, 1937, Low, 1946).

Mode of transmission. Infection is spread from case to case by direct contact, and numerous reports to this effect are on record. Paterson (1841) quotes a case in which lesions developed on the breast of a nursing mother, acquired from similar nodules on her infant's face. He also mentions another instance, in which a man with lesions on his penis communicated the disease to his wife, who developed similar tumors on the vulva; *Nardie (1934) describes an outbreak among a group* of wrestlers Sutton and Sutton (1935) depict an illustration of a patient who contracted multiple lesions on the skin, presumably after being tattooed with an infected needle, Paton (1909) and Spillman *et al.* (1930) reported cases acquired following accidental surgical infection. A case of molluscum contagiosum acquired through coming in contact with an infected woolen garment has also been reported in the literature. The condition can be spread by the hands of cosmetic salon attendants or by masseurs.

Molluscum contagiosum is a relatively common skin disease in Edinburgh, and the figures of Graham Little (see Walker and Percival, 1932) showed that a high proportion of cases occur among those frequenting public swimming baths. The distribution of lesions on the skin of such patients suggested that the infection is acquired through contact with the gymnastic exercising equipment in the swimming baths. The suggestion has also been made that the condition may be carried by some unknown animal or insect vector, and Ehrmann (1892), for example, has incriminated the crab louse *Pediculus pubis*, but this report lacks confirmation Interest in the possible role of animal carriers was aroused by the work of Peterkin (1937), who drew attention to a disease closely resembling molluscum, contracted by shepherds who had handled flocks infected with "Orf," or contagious pustular dermatitis (Rabagliati, 1927, Aynaud, 1923, Howarth, 1929, Berry, 1901, Glover, 1929–30, Selbie, 1944, 1945, 1946 *a*, *b*, Horgan and Haseeb, 1947). Schoch (1939) in America has described a case similar to those of Peterkin, but likens it to sheeppox or cowpox In view of the work of Selbie, Horgan and Haseeb, and others it appears unlikely that the

In view of Peterkin's
material, by corneal scarifi
under observation for six months, but at the end of this time the result was negative

PROPERTIES OF THE VIRUS

Lipschutz (*1911*) measured the elementary bodies (which he called *Strongyloplasma hominis*) occurring in this disease and found that they measured 0 25 μ in diameter in Giemsa-stained films One of us stained the elementary bodies by Paschen's method, and estimated their size to be 0.3 μ when measured by direct photomicrography, and 0 35 μ when calculated by micrometric extinction (van Rooyen, 1938) Electron micrographs show the EB's to be brick-shaped (Ruska and Kausche, 1943). Boswell (1947) found the size to be 302×220 mμ

Recently, we attempted to agglutinate these elementary bodies with the sera of human patients, although a number of tests was performed, we failed to demonstrate the presence of specific agglutinins in these sera The absence of these antibodies may be attributable to the fact that, since the virus grows in the superficial skin epithelium, and does not gain access to the general circulation, it consequently fails to provoke an antibody response This opinion is shared by certain dermatologists, who have asserted that there is no evidence of immunity to molluscum contagiosum, and unless the condition is treated by surgical excision of the lesions, there is no reason why it should not continue indefinitely (Walker and Percival, 1932).

The virus was shown to pass the Chamberland filter by Juliusberg (1905), a Berkefeld filter by Wile and Kingery (1919), and the Berkefeld V and Pasteur-Chamberland and L_1 filters by Findlay (1930). The latter found that the virus retained its activity after preservation in 50 per cent glycerol for one month. Walker and Percival (1932) state that, if a molluscum nodule on human skin is pricked with a needle dipped in carbolic acid, or exposed to the action of x-rays, the condition rapidly heals. It is difficult, however, to decide from such scanty data whether these agents bring about recovery by killing the virus or by stimulating local tissue reaction.

ANIMAL INOCULATION EXPERIMENTS

Among other workers, Goodpasture and Woodruff (1931) attempted to cause infection of rhesus monkeys, as well as other laboratory animals, but with negative results. We ourselves tried to infect a rhesus monkey by intracorneal and intracerebral inoculation, but without success, ferrets and a sheep likewise proved negative. Findlay (1930) reported similar negative results after inoculation of monkeys, anthropoid apes, fowls, and pigeons. Ota and Huang (1934) claimed to have been able to infect rabbits by intratesticular inoculation, but their work lacks confirmation.

Maplestone and Panja (1939) claim to have transmitted the infection to rabbits by the cisternal inoculation of a filtrate prepared from a nodule. The animals died with nervous symptoms.

THE MOLLUSCUM INCLUSION BODY

This is an acidophilic intracytoplasmic structure that is usually circular or pear-shaped, measuring from 20 to 37 μ in diameter, and surrounded by a definite membrane. A number of contradictory views has been expressed with regard to its probable significance, and it was originally thought by Lipschutz (1911) and von Prowazek (1911) to be a parasitic protozoon. On the other hand, Kromayer (1893)

desiccation and fusion of the vacuoles within the cytoplasm of the infected epithelial cell. At the present time, the condition of molluscum contagiosum is regarded as a virus infection, and the molluscum body as a typical inclusion body. Many observers have shown that the molluscum body contains innumerable minute granules, these were originally called *Strongyloplasma hominis* by Lipschütz, their discoverer, but are now recognized to be typical elementary bodies, similar to those found in other virus diseases. Later, Goodpasture and Woodruff (1931) performed comparative micromanipulation studies on the inclusion bodies of fowl-pox and molluscum, they found that, after the cell epithelium had been digested with trypsin, the molluscum inclusions had a sticky covering which resisted dissection with a Chambers' micromanipulator.

According to one of us (van Rooyen, 1938), the molluscum body grows from a minute elementary body which enters the cell. He does not agree that the inclusion is developed from fusion and desiccation of the vacuoles in the cytoplasm of the infected epithelial cell, and suggests that the vacuoles are formed by degenerative changes set up within the cell, due to the growth of the inclusion body therein. A number of observations was also made (van Rooyen) on the shape, size, and structure of the inclusions, it was shown that they may be either small and circular in outline, measuring about 20 μ in diameter, or alternatively, larger oval or pear-shaped in contour, attaining a maximum size of 37 μ in their long axis, it was suggested that these larger forms probably represent the more mature developmental stages of the parasite. The large pear-shaped molluscum bodies were

also demonstrated to possess a surrounding membrane, thickest at the broad segment end, and thinnest at the other pole, where it resembled a cap

By microdissection it was proved (van Rooyen) that the conical thin-walled pole of the body could be readily ruptured by incision with a microdissecting needle point, and that the interior of the molluscum body contained numerous elementary bodies suspended in a gelatinous fluid.

We believe that, in miniature, the molluscum body presents certain morphological resemblances to the sporangium of a fungus parasite such as *Rhinosporidium seeberi* (Wernicke, 1903, Ashworth, 1923); this parasite causes a polypoidal affection of the nasal mucosa, and is accompanied by the formation of large cysts in the tissues Like the molluscum body, the *Rhinosporidium* cyst has also a wall or membrane which possesses a weakened exit pore, and contains numerous spores suspended in a mucoid substance In view of these new findings, the question arises *as to what is the precise biological classification of the molluscum inclusion body*, but much further work is necessary before the matter can be discussed fully.

The chemical composition of the molluscum body has recently been investigated by one of us and the results have suggested that the outer covering of the inclusion is probably composed of carbohydrate material Thus, after staining the inclusion bodies with iodine solution the color could be made to disappear by warming the slide, and reappear by permitting to cool Furthermore, the iodine-reacting properties of the molluscum body could be permanently removed by subjecting films to the digestive action of fresh human saliva, but not boiled saliva Microincineration studies were also conducted, and it was found that the concentration of calcium salt in the ashed inclusions was greater in amount than in the surrounding body tissues (van Rooyen, 1939).

LABORATORY DIAGNOSIS AND SPECIFIC TREATMENT

If the area of the skin bearing the tumor is tender, it should be anesthetized with cocaine or frozen with carbon dioxide snow, before attempting to avulse the lesion with forceps The nodule should be squeezed with the forceps, the milky exudate placed on a glass slide, a drop of liquor potassii added, a coverglass placed over it, and the preparation viewed under the dry high-power objective of the microscope If molluscum bodies are present, they are usually found in large numbers If it is desired to stain the bodies in wet films, to render them more conspicuous, we recommend that a drop of Lugol's iodine should be substituted for liquor potassii solution, after such treatment the bodies will appear as large, oval, deeply stained brown masses A drop of 1 2,000–25,000 dilution of brilliant cresyl blue made up in 0 86 per cent saline solution gives even better results, the dye exhibits a selective staining action on the molluscum body, which appears as a large blue mass inside the cytoplasm of the infected epithelial cell

Maplestone and Panja (1939) claim to have demonstrated fixation between convalescent serum and antigen prepared from infected rabbit brain

There is no specific treatment Brain (1937) has tried vaccines consisting of an extract made from molluscum lesions, but has failed to show any therapeutic benefit. It has been found that the oral administration of sulfonamide has an inhibiting effect on the progress of the lesions (Somerville, 1941, Hill and Downing, 1942, Laymon, 1946).

CHAPTER XV

WARTS (VERRUCAE)

CLINICAL FEATURES

THE INCUBATION PERIOD is long, as has been proved by various observers who have carried out human inoculation experiments with wart material and found the following periods to elapse before the development of growths 1 month (Wile and Kingery, 1919), 6 months (Kingery, 1921); 8 months (Findlay, 1930); 90 days (Brunschwig, Tschetter, and Hamann, 1940); and 20 months (Templeton, 1935).

A number of types of wart varying somewhat in appearance, selective site, and age preference is described. It is becoming increasingly evident, however, that the etiological agent is the same in all, and that inoculation of material from one type of wart can, under suitable conditions, give rise to those of another type

(*a*) *Common warts* occur mainly on the hands as discrete, rounded, or oval growths of gray color and dry appearance. On occasions they are found elsewhere on the skin A modification of this type of wart is found on the palms or soles (palmar or plantar warts) The plantar wart occurs in athletes (Sutton and Sutton, 1935), and in schoolchildren, particularly girls (Halberg, 1936, Lomholt, 1936, MacKenna, 1938). The weight of the body causes this type of wart to become depressed below the surrounding skin level, and so to occupy a cup-shaped cavity covered with a hard epidermal "lid." This lid can be removed to disclose a soft necrotic center which overlies the skin papillae. Plantar warts are favored by flat feet, and the lesions occur chiefly on the ball of the foot and the heel

A special form of the plantar wart is the mosaic wart In this condition there are small, dry warts which are very resistant to therapy.

(*b*) *Juvenile* (*plane*) *warts* are smaller than the above and occur together in groups. In shape they are flatter than the common wart and are most commonly found on the face and dorsum of the hand

(*c*) *Digitate warts* are pedunculated growths broken up into leaf-like folds, each tipped with hardened epithelium, they are found on the face and scalp

(*d*) *Filiform warts* are small delicate tufts of growth found on the eyelids and sometimes the neck They are common on the neck in women.

(*e*) *Genital warts* It has been suggested (Wilson, 1937) that this term should be used to cover those conditions often known variously as moist warts, fig warts, gonorrheal warts, venereal warts or vegetations, and condylomata lata At one time it was thought that such warts were of different etiology to ordinary skin warts, but it has been shown repeatedly, following the original work of Waelsch in 1918, that this is not the case This observer inoculated genital wart material intradermally, with production of a typical plane wart Despite this observation many venereologists and others still contend that gonorrhea may cause some of these warts, but it is more likely, however, that the only effect of gonorrhea is that the purulent discharge causes irritation of the wart with consequent increase in size, and perhaps superficial ulceration Genital warts increase in size during pregnancy but decrease thereafter. In the male they appear as small grayish rough nodules in the coronal sulcus or subpreputial region In the female they are found on the labia and around the vulval orifices and, owing to the greater moisture of the parts, assume large [illegible] ion occurring [illegible] in the anal and axillary regions,

(*f*) *Laryngeal papillomata* may be single or multiple, either flat-based or pedunculated, and white or red in color, the surface is rough and mamillated The classi-

cal work on the etiology of this condition is that of Ullmann (1923) who demonstrated the following points he reproduced a flat wart on his own arm with an extract made from a laryngeal papilloma; he reproduced flat warts on the skin of the face in 3 out of 4 children, he demonstrated the filtrability of the virus (although he did not specify the filter used), he transmitted the infection to the vagina of a bitch, and in sections of this lesion described intranuclear eosinophilic inclusions similar to those of herpes febrilis. Ishikawa (1936) has reproduced warts in man and in the oral and vaginal mucosae of dogs with extracts from human laryngeal papillomata, thus confirming the original work of Ullmann

HISTOLOGY

Full histological descriptions of warts are to be found in the works of Unna (1896) and McCarthy (1931).

The Common Wart

Unna recognized 3 distinct stages of every wart

(*a*) *Stage of commencement.* Simultaneous acanthosis and hyperkeratosis result in the affected papillae being depressed, flattened, and stretched. The earliest stage is, therefore, that of a pure acanthoma

(*b*) *Stage of acme.* Hitherto the cutis has remained comparatively unaltered, but now epithelial ridges begin to grow inward. The cutis responds with inflammatory changes of a mild character, and opposes the entrance of the ridges, which become bent This growth of the epithelium results in a change of shape of the papillae, which acquire a broad fixed end and combine into a common papillary trunk. The prickle cells are active, considerably swollen, and show numerous mitotic figures, the granular layer also is thicker than normal. Between the papillae there is an increased granularity due to an exaggeration of the normal process of formation of keratohyalin.

(*c*) *Stage of regression.* There is no further growth of prickle cells, but cornification continues and extends deeper and deeper, tears and cracks appear, and some horny tissue is cast off. Eventually the papillae are disclosed, covered in horny tissue and resembling expanded fingers which turn out, thus drawing attention to their constricted bases.

Juvenile Warts

The histological changes are less severe than the above and are limited entirely to the epithelium A considerable hyperkeratosis is found at all stages Acanthosis is of slight degree at first but becomes more and more pronounced with age (McCarthy, 1931)

Genital, Filiform, and Digitate Warts

These warts have a somewhat similar histological appearance (Unna, 1896)

(*a*) There is a patchy thickening of the epithelium which projects in one or more points, due to swelling of the subjacent cutis

(*b*) In both common and genital warts the preliminary acanthosis flattens out the papillae In the former this condition persists, but in the latter the number of papillae steadily increases by branching, a chronic inflammatory cellular exudate is found in these new-formed papillae.

(*c*) The covering epithelium shows very active growth of the prickle cells, but there is no hyperkeratosis, consequently, marked furrowing of the surface results, with shedding of the horny layer, and this accounts for the soft appearance of larger genital warts

SPREAD OF WARTS

It has long been known by the laity that if warts are made to bleed, then spread is liable to occur to neighboring parts of the skin The infectivity of warts was

originally proved experimentally by workers many years ago (e.g., Variot, 1894; Jadassohn, 1896, Juliusberg, 1903). Warts may be spread from case to case by direct contact; in shaving, by water; by flooring, e.g., in bathing-pools and school lavatories (Lomholt, 1936), by the chiropodist's instruments if improperly sterilized (Sutton and Sutton, 1935); and by the hairdresser's brushes and combs (Cranston Low, 1934). A group of related cases occurred in a factory where glue had become infected with the virus from one of the workers (McLaughlin and Edington, 1937). Genital warts are spread venereally.

ANIMAL WARTS

Warts of similar appearance to those of human beings occur naturally in dogs and cattle. The virus of dog warts is known to be filtrable, but is not transmissible to man (Findlay, 1930) The virus of cattle warts is also filtrable (Magalhães, 1920), as regards transmission to man, Schultz (1908) obtained positive results, but Soule and McKinley (1930–1) failed to confirm his observations.

EVIDENCE FOR A COMMON ETIOLOGY OF WARTS

Human warts. On clinical grounds there is considerable likelihood of the similarity, if not actual identity, of the infecting agents of the different types of human wart, for the following reasons common and plane warts are frequently found together in the same patient; genital warts and other types of wart frequently coexist, laryngeal papillomata are frequently associated with plane warts of the face. Scientific investigations have shown that genital warts (Waelsch, 1918) and laryngeal papilloma extracts (Ullmann, 1923, Ishikawa, 1936) both give rise to flat warts on intradermal injection. As regards plantar warts, the general consensus of opinion is that these are due to the same agent as the other types, being frequently coexistent. It has, however, been suggested by Goldsmith (1936), who saw an epidemic of plantar warts without any other lesions, that the virus may be distinct. *It should also be noted that warts of any variety frequently* "breed" true to type in any one person.

Animal warts. These warts do not appear to be transmissible to man and probably there is a specific virus, both for dog and for cattle warts

PROPERTIES OF THE WART VIRUS

Animal inoculation. Despite numerous attempts to transmit the virus to animals, the only definite results have been obtained in the case of laryngeal papillomata, Ullmann (1923) and Ishikawa (1936) have transmitted this infection to the vagina of bitches Wilson (1937), working with genital warts, has, however, suggested that the rabbit's testicle may prove a favorable site for injection, and this should be further investigated It has not proved possible to infect the rabbit by cutaneous, subcutaneous, or mucosal inoculation (Brunschwig, Tschetter, and Hamann, 1940, Callomon, 1942) The virus of verrucae may on occasions hasten the malignant degeneration of "warts" produced on the rabbit's ears by benzpyrene (*Brunschwig, Tschetter, and Hamann, 1940*)

Morphology and filtrability Elementary bodies have not been described With regard to inclusion bodies, the increased eosinophil granularity of the superficial layers of the wart has already been considered These granules have undoubtedly deceived certain workers who have suggested that they are specific inclusion bodies (e.g , Sangiorgi, 1915) For any eosinophil granules to be seriously regarded as specific inclusion bodies, however, they should be demonstrable in the basal layers of the skin, normally free from such particles Further, they should be carefully studied in preparations stained by the Feulgen technique for thymonucleic acid and by the MacCallum test for masked iron, to exclude a nuclear origin, as well as by the oxidase reaction, to exclude a possible derivation from leukocytes Wilson (1937) has demonstrated large granular eosinophil bodies in the malpighian and

basal layers which bear considerable resemblance to Guarnieri, Bollinger, Marchal and other inclusions, but these bodies, before they can be accepted as specific, require further investigation.

As regards nuclear inclusions, it is difficult to reach any definite conclusion Ullmann (1923) described intranuclear inclusions in the cells of a papilloma produced in the vagina of a bitch, which bodies resembled the Lipschütz bodies of herpes Lipschutz has described the presence of both basophilic (1924 *a*) and eosinophilic (1924 *b*) bodies in acuminate and common warts, but these are probably of degenerate nature Wilson (1937) has also found eosinophilic intranuclear inclusions in genital warts

The virus of human warts was first shown to be fitrable through a Berkefeld N candle in 1907 by Ciuffo. This observation has been confirmed with Berkefeld candles of all grades of porosity (Wile and Kingery, 1919, Kingery, 1921; Findlay, 1930).

Reaction to physical and chemical agents. The virus withstands 50 per cent. glycerol (Findlay, 1930) and may, therefore, be preserved in this solution in the refrigerator. It also survives a temperature of 50° C. for half an hour (Templeton, 1935).

IMMUNITY AND TREATMENT

Warts frequently disappear spontaneously, but whether this be due to increase in antibody content of the serum has not been determined Brain (1937) could not demonstrate any antibody in the serum of patients Maderna (1935), however, has shown that complement fixation occurs between wart antigen (made by grinding warts in saline after glycerolization) and the serum of cases of warts.

Findlay (1930) states that he became immune to further infection after three separate inoculations of wart material, so presumably active immunity can be acquired

Maderna (1934) has described a skin reaction of similar type to the Frei test. Wart antigen is injected intradermally and a papulopustular reaction develops

Warts are usually treated by local means directed toward causing them to shrivel up No success has attended the injection of wart vaccines (Brain, 1937) When one wart is destroyed, others may also regress.

CHAPTER XVI

HERPES ZOSTER (ZONA, SHINGLES)

CLINICAL FEATURES

Predisposing Causes

Although probably the majority of cases of zoster is "idiopathic" or primary, in some a predisposing cause may be found. Thus, secondary zoster occurs after administration of arsenic or bismuth, and in cases of carbon monoxide poisoning, sulfonamides have also been blamed (Attmeyer, 1939). It is also found in cases of pulmonary tuberculosis, malaria, pneumonia, and cerebrospinal fever, it is sometimes related to trauma (see Jadassohn, 1938), and has occurred after the patient has been struck by lightning (Parfitt, 1936). A case has been reported where bilateral zoster of the buttocks followed suboccipital injection of lipiodol (Urechia, 1938); zoster has followed the administration of a spinal anesthetic (Arnold, 1941). In some of these cases it is questionable whether one is not really dealing with a primary zoster occurring by chance in one of the conditions mentioned

Another group of cases developing zoster is that where the spinal cord or column is affected by a disease such as tabes, acute myelitis, spinal tumor, or caries (Kobro, 1940, Mumme, 1941). Zoster may occur in the area of referred pain in cardiac infarction or angina (Parsonnet and Bernstein, 1939, Spillane and White, 1939)

Leukemia, lymphadenoma, or lymphosarcoma may lead to zoster, possibly due to [illegible] ëri *et al*, 1937, [illegible] Poulsen, 1939, [illegible] Catlin, 1946). Marques (1938) has reviewed the literature on the association of zoster and leukemia and finds that it is more frequent in the lymphatic type It may be stated here that both primary and secondary zosters are regarded as being due to the same virus.

Incubation Period

The most reliable information is probably that supplied in various experiments (mentioned below) where the following periods have been found to elapse between the injection of zoster fluid and the development of local vesicles 9 to 12 days (Kundratitz), 7 to 14 days (Bruusgaard), 21 days (Siegl).

Course of the Disease

During the last few days of the incubation period the patient, particularly if young, may be pyrexial, and neuralgia may be experienced in the area which is soon to be affected Various respiratory and digestive disturbances may occur. The rash appears first at the point where the cutaneous nerves come to the surface, and spreads therefrom It has been said that the spread of the lesion occurs distally, along the distribution of the nerve (Stern, 1937). At first the rash is erythematous, but vesiculation soon takes place After 5 to 10 days these vesicles have usually dried up and formed scabs, in very severe cases gangrenous change may occur. Small "aberrant" vesicles may be found in other parts of the body apart from the area mainly involved Some scarring usually remains after the rash has healed Pain, always severe during the rash, may persist for weeks or months, and in elderly persons is specially liable to recur in cold weather In certain cases anesthesia of the affected part may be found

(*b*) *Endocarditis* A case of cervicothoracic zoster has been recorded which was followed in 7 days by endocarditis (Andréassian, 1934).

(*c*) *Nervous complications.* The central nervous system is probably involved to some extent in most

cytosis and an increase c

1902; Schussler, 1935;

of zoster and must

1899). It is of the

the anterior horn

cells It rarely occurs in zoster of the trunk, although a few cases of muscular paralysis, usually of the abdominal wall, are recorded (e g, by Taylor, 1895; Hewlett, 1906, Soderbergh, 1919; Worster-Drought, 1923, Gais and Abrahamson, 1939). Zoster of the upper limbs is more commonly associated with muscular paralysis than is zoster of the lower limbs, in fact, paralysis of the lower limbs is exceedingly rare (see Ebstein, 1895; Parkes Weber, 1915, 1916, Chandler, 1935, Wilson, 1941, Parkinson, 1948).

Cranial nerve paralysis usually affects the facial nerves, alone or with others (see, e g, Ebstein, 1895, Spota and Alurralde, 1937, Kramer, 1938, Wilson, 1941) Rebattu *et al.* (1933) found facial paralysis in almost 50 per cent. of cases of cephalic zoster, and it was of the Bell or peripheral type Ramsay Hunt suggested that paralysis of the facial nerve associated with an eruption in the external auditory meatus was due to involvement of the geniculate ganglion; Denny-Brown, Adams, and Fitzgerald (1944) reported a case of this type where the geniculate ganglion was quite unaffected, the second cervical ganglion showed inflammation, and there was a motor neuritis of the facial nerve. O'Neill (1945) reviews the question of zoster auris, and concludes that it is not uncommon He found no evidence that Hunt's syndrome is necessarily associated with geniculate ganglionitis, it may be associated with involvement of the trigeminal, second cervical, and vagal ganglion. Tschiassny (1946) also reviews Hunt's syndrome, and concludes that if facial palsy is associated with a facial or occipitocollaris eruption the nerve lesion is not in the geniculate ganglion, if the eruption is on the "geniculate" zone of the external ear, the nerve lesion is to be found in the geniculate ganglion Paralysis of the ocular muscles is said to occur in some 7 per cent. of cases of zoster ophthalmicus (Hewlett, 1906) This condition of paralysis has been recorded by a number of authors, some of whom note its occasional association with hemiplegia (Parkes Weber, 1915, 1916, MacGillivray, 1931; André-Thomas and Buvat, 1931, Rebattu *et al*, 1933, Carmody, 1937, Perrin *et al*, 1938) The internal ocular muscles are usually involved along with the external, recovery occurs in 2 to 3 months

1895) or

bosis or

Meningit

meier, 1940, Michalovici, 1941).

Meningo-encephalitis, or encephalitis has been described in a number of cases (see Schiff and Brain, 1930, Brain, 1931, Biggart and Fisher, 1938, Gais and Abrahamson, 1939, Parat, Maffei, and Lewi, 1939, Hassin and Rabens, 1944, Gordon and Tucker, 1945, Krumholz and Luhan, 1945)

Schiff and Brain, in an extensive review, mention three possibilities to account for meningo-encephalitis (1) a pure coincidence, as supported by Netter (1930), who reported a number of cases which he considered to be encephalitis lethargica complicating zoster, (2) a pre-existing meningo-encephalitis of undetermined etiology is the primary condition which damages the sensory nerves, thus causing an attack of secondary zoster, (3) zoster virus spreads from the posterior roots and causes meningo-encephalitis In all probability all three possibilities may occur, and

Varieties of Zoster

(*a*) *Bilateral zoster* is uncommon, usually only one side being involved (see Rattner, 1938, Ambler, 1939).

(*b*) *Zoster of the trunk* is the commonest of all types, and probably the thoracic portion is more commonly involved than the abdominal. Hewlett (1906) estimated that 76 per cent. of cases of zoster affect the trunk, and Stern (1937) has found the posterior part to be more extensively involved than the anterior.

(*c*) *Cephalic zoster*. The subject of cephalic zoster has been treated most comprehensively by Rebattu *et al.* (1933), whose paper should be consulted by all interested (for an English summary see *Arch. Neurol. Psychiat.*, 1934, 31, 1101, 1297). Zoster of the head and neck may affect the cervical, facial, buccopharyngeal, ophthalmic, and auricular regions, and certain syndromes are well recognized. Thus, trigeminal zoster affects the distribution of the fifth cranial nerve, and the gasserian ganglion is severely involved Vesicles occur on the forehead, sides of the nose, and face. The cornea may be gravely affected (zoster ophthalmicus) when the nasociliary branch is involved in the inflammatory process. Zoster ophthalmicus presents a variety of appearances such as keratitis, scleritis, and iridocyclitis (see Duke-Elder, 1938, Viallefont, 1939, Edgerton, 1942; Parry and Laszlo, 1943; Neame, 1944). Zoster oticus is manifested by the occurrence of vesicles on the fauces, uvula, or tongue. The preauricular gland is enlarged, and facial and laryngeal paralyses may occur. The condition is extremely painful (see Kelly, 1940; Rosenberger, 1941, Watson, 1941). Various other paralytic manifestations may complicate cephalic zoster, such as lingual paralysis, facial paralysis (*vide infra*), and auditory or vestibular disturbances Ramsay Hunt described the "geniculate syndrome" of facial paralysis, auricular herpes, with or without deafness, tinnitus, and vertigo (see Denny-Brown, Adams and Fitzgerald, 1944), and below.

(*d*) *Genitory-urinary zoster*. Zoster of the external genitalia and the urethra is not uncommon. Zoster of the urinary bladder is, however, extremely rare. Chesterman (1932) recorded a case associated with a typical eruption on the gluteal region, and Rinker (1941) one without skin lesions

(*e*) *Recurrent idiopathic zoster* is also an extreme rarity. Cases have been recorded where a recurrence took place several years after the first attack and usually on the opposite side of the body (Graham-Little, 1937), the same site may be reaffected even within 12 months (Hruszek, 1934)

(*f*) *Zoster generalisatus seu varicellosus* This condition has been described by a number of authors (e g, Fasal, 1909, McEwen, 1920, Parounagian and Goodman, 1923, Levaditi, 1926, Stein, 1928, Davidson, 1934, Hourand, 1938, Barker, 1939, Ferriman, 1939, Fleming, 1939, Seremini, Herrera-Ramos and Isasi, 1939, Campbell, 1941, Wilson, 1941, Director, 1944, Taylor, 1945, Sharpe, 1946). Most of the cases occur in elderly persons in whom, a few days after the ordinary zoster vesicles have appeared, a profuse and widespread vesicular eruption occurs. The case therefore resembles varicella, but the characteristic polymorphism of the lesions of this condition is usually lacking, and serves to distinguish between the two (Hutton, 1935) *These cases frequently give rise to outbreaks of varicella in contacts* and also to other cases of zoster The condition is a borderline one between zoster and varicella and is probably caused by a strain of virus with marked dermotropic properties, tending to resemble closely strains isolated from cases of true varicella, a number of authors regards the condition as being rather a modified varicella than a virulent zoster

Complications of Zoster

(*a*) *Zoster arthritis* The fingers are usually affected, the onset coinciding with that of the eruption Pain and swelling are severe, and movement is greatly limited (Brain, 1931)

(*b*) *Endocarditis*. A case of cervicothoracic zoster has been recorded which was followed in 7 days by endocarditis (Andréassian, 1934)

(*c*) *Nervous complications*. The central nervous system is probably involved to some extent in most cases, for the cerebrospinal fluid regularly shows lymphocytosis and an increase of globulin (Brissaud and Sicard, 1901; Chauffard and Froin, 1902; Schussler, 1935; Gais and Abrahamson, 1939). These changes are more mar

zoster and must be

899). It is of the lower motor neurone type and probably due to involvement of the anterior horn cells. It rarely occurs in zoster of the trunk, although a few cases of muscular paralysis, usually of the abdominal wall, are recorded (e g., by Taylor, 1895, Hewlett, 1906; Söderbergh, 1919, Worster-Drought, 1923; Gais and Abrahamson, 1939)

Zoster of the upper limbs is more commonly associated with muscular paralysis than is zoster of the lower limbs; in fact, paralysis of the lower limbs is exceedingly rare (see Ebstein, 1895, Parkes Weber, 1915, 1916, Chandler, 1935; Wilson, 1941, Parkinson, 1948).

Cranial nerve paralysis usually affects the facial nerves, alone or with others (see, e g, Ebstein, 1895; Spota and Alurralde, 1937, Kramer, 1938, Wilson, 1941). Rebattu *et al.* (1933) found facial paralysis in almost 50 per cent. of cases of cephalic zoster, and it was of the Bell or peripheral type Ramsay Hunt suggested that paralysis of the facial nerve associated with an eruption in the external auditory meatus was due to involvement of the geniculate ganglion, Denny-Brown, Adams, and Fitzgerald (1944) reported a case of this type where the geniculate ganglion was quite unaffected, the second cervical ganglion showed inflammation, and there was a motor neuritis of the facial nerve. O'Neill (1945) reviews the question of zoster auris, and concludes that it is not uncommon He found no evidence that Hunt's syndrome is necessarily associated with geniculate ganglionitis, it may be associated with involvement of the trigeminal, second cervical, and vagal ganglion Tschiassny (1946) also reviews Hunt's syndrome, and concludes that if facial palsy is associated with a facial or occipitocollaris eruption the nerve lesion is not in the geniculate ganglion, if the eruption is on the "geniculate" zone of the external ear, the nerve lesion is to be found in the geniculate ganglion Paralysis of the ocular muscles is said to occur in some 7 per cent of cases of zoster ophthalmicus (Hewlett, 1906). This condition of paralysis has been recorded by a number of authors, some of whom note its occasional association with hemiplegia (Parkes Weber, 1915, 1916; MacGillivray, 1931, André-Thomas and Buvat, 1931, Rebattu *et al*, 1933; Carmody, 1937, Perrin *et al*, 1938) The internal ocular muscles are usually involved along with the external, recovery occurs in 2 to 3 months. The cord may be involved, with symptoms of ascending myelitis (Ebstein, 1895) or transverse myelitis (Gordon and Tucker, 1945) It is possible that thrombosis or hemorrhage is responsible for this type of case (Gordon and Tucker) Meningitis has been reported by a number of workers (see Molari, 1939, Brundlmeier, 1940, Michalovici, 1941)

Meningo-encephalitis, or encephalitis has been described in a number of cases (see Schiff and Brain, 1930, Brain, 1931, Biggart and Fisher, 1938, Gais and Abrahamson, 1939, Parat, Maffei, and Lewi, 1939, Hassin and Rabens, 1944, Gordon and Tucker, 1945, Krumholz and Luhan, 1945)

Schiff and Brain, in an extensive review, mention three possibilities to account for meningo-encephalitis (1) a pure coincidence, as supported by Netter (1930), who reported a number of cases which he considered to be encephalitis lethargica complicating zoster, (2) a pre-existing meningo-encephalitis of undetermined etiology is the primary condition which damages the sensory nerves, thus causing an attack of secondary zoster, (3) zoster virus spreads from the posterior roots and causes meningo-encephalitis In all probability all three possibilities may occur, and

Schiff and Brain themselves quote a case of meningo-encephalitis definitely due to the virus of zoster.

Biggart and Fisher's case also suggested that the encephalitis was due to a direct upward spread of the virus, for the autopsy disclosed a dorsal root ganglionitis, a posterior myelitis, and an encephalitis. Perivascular infiltration with lymphocytes occurred in the dorsal half only of the cord, and there was also a diffuse interstitial increase of cells in the posterior horns. Perivascular infiltration was found in the medulla, subcortical cerebellar nuclei, thalamus, hypothalamus, and parietal region.

Krumholz and Luhan found a relatively mild nonpurulent encephalitis of the medulla oblongata, but no infiltrative inflammatory changes in the brain above the medulla. In the cortex, they [illegible] nature of a secondary and "allergic" [illegible] does not occur. The hemiplegia a[illegible]cially the cephalic variety, may be due to a localized thrombosis or hemorrhage produced by the zoster virus (see Gordon and Tucker, 1945).

PATHOGENESIS

The portal of entry of the virus is unknown, and various routes have been suggested. Haslund (1900) pointed out that the disease may be ushered in with upper respiratory symptoms, sore throat, angina, and the like, and suggested, therefore, that the virus enters the body through the tonsils. Thereafter it is carried in the blood stream to one or more spinal ganglia, and in certain cases to the skin also, thus explaining the production of "aberrant" vesicles. Low (1919) suggested that the virus spreads from the nose by the olfactory perineural lymphatics to the meninges and cerebrospinal fluid, and thence to the spinal ganglia.

Neither of these theories explains the specific localization of the virus in particular spinal or other ganglia. To account for this, one of the most striking features in the pathology of the condition (*vide infra*), Montgomery (1921) suggested that the virus enters the nerve endings in the skin and ascends along the nerve sheath in the lymph spaces until it reaches the appropriate ganglion. In our opinion, this theory is the most tenable of the three, and is supported by certain clinical findings. Thus, regional lymphadenitis limited usually to one gland draining the site of eruption is a constant feature, usually disappearing by the seventh day (Raymond and Lebel, 1920, Rebattu *et al.*, 1933). Further, for some days before the appearance of the eruption, neuralgia, hyperesthesia, and paresthesia occur in the region supplied by the nerve, possibly due to some irritant action of the virus ascending therein. While Montgomery suggests that the virus ascends in the nerve, Stern (1937) suggests the reverse. Thus, when in cases of thoracic zoster he injected the appropriate intercostal nerve with alcohol, the skin became anesthetic, but no cessation of the spread of the lesion was observed. Further, in early cases of zoster he found the lesions to spread distally along the course of the nerve. Accordingly he suggested that the eruption was probably caused by some substance traveling slowly down the nerve. He does not indicate, however, how the virus reaches the central position in the first place.

Any theory of the pathogenesis of zoster must endeavor to explain the quite common occurrence of paralytic complications (this subject has been extensively dealt with by Rebattu *et al.*, 1933). The most likely explanation of why these cases occur is that the inflammation in the posterior horns or roots spreads forward to involve the anterior horns or roots. This theory of the central origin of the paralysis does not fit all cases, however, and Montgomery (1921) considers that the paralysis is peripheral. He suggests that the virus enters by the skin, and although usually ascending in a sensory nerve, it may sometimes attack a motor nerve, causing paralysis. Montgomery believes that the reason why paralysis is commonly associated with zoster of the extremities is that the terminal motor nerves are situated so superficially that the virus can enter readily. Paralysis is

said to be more rarely associated with thoracic zoster because here the motor nerves are less easily accessible. The comparative frequency (7 per cent. of cases, Hewlett, 1906) with which cases of zoster ophthalmicus are associated with paralysis of the eye muscles also lends support to Montgomery's theory, as he finds that it is the most superficial nerve, the oculomotor, that is more commonly involved than is the deeper trochlear or abducens. The cases which most definitely suggest a peripheral origin of the paralysis are like those described by Roblin (1920), Rebattu *et al.* (1933), and Masser (1937), who observed facial paralysis associated with cephalic zoster. The paralysis was of the superficial or Bell type, thus suggesting that the virus had attacked the nerve peripherally rather than centrally.

A further point to be discussed concerns the mechanism of production of secondary zoster. In cases where zoster follows on trauma or some infective condition, it seems necessary to postulate that the virus has been latent somewhere in the body and has been stimulated into activity. The site of such latent infection is not known, but perhaps it is in the upper respiratory tract.

In conclusion, we may say that it is probable that the eruption is caused in some way by involvement of the spinal and perhaps certain other ganglia, but as to how the virus reaches these ganglia is unknown. In the present state of knowledge it would be unwise to express an opinion as to whether the spread of infection is centripetal or centrifugal. Montgomery's theory is of interest—that the virus usually ascends sensory nerves to reach the ganglia, and that sometimes it ascends motor nerves, with the production of paralysis.

HISTOLOGY

The vesicle. The histology of the zoster vesicle has been fully described, in particular by Unna (1896), Lipschutz (1925), and McCarthy (1931). The primary change is said to be an affection of the cells in the deeper malpighian layers, some of which proliferate to form giant multinucleated cells. Others undergo marked swelling and form "balloon cells," which stain well only around the periphery, nuclei being seldom discernible. Neighboring areas undergo degeneration, and a unilocular intercellular vesicle results from their fusion. The edematous content of these vesicles increases and forces apart the walls, which are composed of degenerate "balloon cells." Multilocular vesicles may also be found, these are initially intracellular, and form inside "balloon cells," being bounded only by a thin rim of cell wall. The ultimate result is that a multiloculated vesicle is formed by the fusion of a number of these cells.

The fully formed zoster vesicle usually shows both types of change. It is covered over by a layer of horny cells and may rest on the uncovered papillary bodies. If it is of large size the contents of the vesicle may remain serofibrinous with a few polymorphs or else a marked purulent reaction may develop both in the vesicle and surrounding parts. In such cases the dermis shows an inflammatory reaction, being infiltrated with pus cells and lymphocytes.

Inclusion bodies were first described by Lipschutz (1921 *a*, *b*, 1925), but these cannot be found in every case (McCarthy, 1931). They occur intranuclearly, in the epithelial "balloon cells" around the base of the vesicle as well as in connective tissue cells. They are acidophilic and may fill the whole nucleus, but are usually

(1938) have reported the presence of small granular inclusions both in the nucleus and cytoplasm of epithelial cells in the zoster vesicle. These bodies resemble

exactly those reported by the same authors in herpes febrilis (see p. 184). Dahl (1944) has also described EB's.

Healing of the vesicle eventually occurs by crusting, the crust being detached by the growth of subjacent epithelial cells.

The nervous system. The essentially nervous basis of zoster was first recognized by von Barensprung (1862). The classical work on the subject is that of Head and Campbell (1900), who pointed out the uniform involvement of the spinal ganglia and other parts of the primary sensory neurone; they also emphasized the essential pathological unity of both primary and secondary zoster. Usually only one spinal ganglion is affected, showing a marked cellular infiltration, mainly with small mononuclears, both in its capsule and parenchyma. Hemorrhage may also occur with more or less destruction of the ganglionic nerve cells. Healing eventually occurs with secondary gliosis This severe ganglionic lesion naturally affects the other parts of the neurone, the peripheral nerves showing degeneration of those fibers whose nerve cells have been involved in the ganglion, and the posterior nerve roots and columns showing degeneration followed by secondary sclerosis The nerves supplying the affected area of skin may be congested and infiltrated with small round cells (see e g, Charcot, 1889, Marinesco, 1931, Marinesco and Draganesco, 1932, Stern, 1937). Wohlwill (1924) has drawn attention to the posterior poliomyelitis uniformly present in cases of zoster, which is shown by a monocytic infiltration of the posterior horns and even of the bulb and cerebral peduncles Lhermitte and Nicholas (1924) also drew attention to inflammatory, degenerative changes in the posterior horn, and describe similar changes in the anterior horn.

It is evident that herpes zoster cannot be regarded as a mild affection of the skin and spinal ganglia only, as severer nervous changes probably occur in all cases. More recently Denny-Brown, Adams, and Fitzgerald (1944), who examined the spinal ganglia and other portions of the nervous system in 3 cases, drew attention to four histological features distinguishing zoster· (1) ganglionitis marked by pannecrosis of all or part of the ganglion, with or without hemorrhage and surrounded by intense lymphocytic infiltration, and associated with the vesicular eruption in the corresponding cutaneous segment, (2) unilateral myelitis, limited to 2-3 segments, and involving chiefly the posterior horn and root, and dorsal spinal ganglia, some changes are found in anterior horn cells, (3) localized leptomeningitis limited to involved spinal segments and nerve roots, (4) true peripheral mononeuritis, seen not only in the nerves distal to the ganglion but in the anterior nerve root, both within the meninges and in the portion contiguous to the involved spinal ganglion

EPIDEMIOLOGY

As regards sex, males are said to be slightly more commonly affected than females No age period is exempt, but the majority of cases occurs in adults from 20 to 60 (Rivers and Eldridge, 1929 *a*) A case has been described in a 3-day-old infant (Freud, Rook, and Gurian, 1942) Figures have been brought forward to show that the greatest number of cases occurs in the autumn and June (Bokay, 1928) A number of epidemics of zoster has occurred, usually in barracks or schools (see Fuhlrott, 1920, Levaditi, 1926) How the infection is spread from case to case is not known, but as many cases apparently arise spontaneously, or secondarily to some exciting factor, it is probable that the virus may be carried on the skin, in the respiratory passages, or elsewhere in the body. Cases certainly arise in contacts of zoster or varicella, so infection may be spread, presumably, by droplets, direct contact, or fomites It is probable also that human carriers exist (Wooley, 1946)

PROPERTIES OF THE VIRUS

Inoculation Experiments

Human experiments. Zoster fluid injected into the skin of adults will not reproduce the infection (Meineri, 1922). A number of workers has shown, however, that zoster fluid injected intradermally into children under 5 years of age often produces a crop of vesicles Kundratitz (1925 *a*, *b*; Lipschutz and Kundratitz, 1925) was the first to demonstrate this infectivity, which had previously been suggested on purely clinical grounds by Landouzy in 1884. Thus, in one series Kundratitz injected 28 normal children with fluid from 6 cases of zoster, and after an incubation period of 9 to 12 days local papules and vesicles developed in 17 cases, and in 3 of these typical varicella occurred. Numerous other authors have confirmed these findings, both with regard to the production of local lesions and of varicella (see Siegl, 1927, Netter, 1928, who gives a number of references, Cleveland, 1927, Bruusgaard, 1932) The experiments of Bruusgaard are of particular interest. A child was injected with zoster fluid, and 7 days later varicella-like vesicles developed locally. The fluid from these vesicles produced, 14 days after intradermal injection, a generalized varicelliform eruption in another child Further, this child's brother developed typical varicella 14 days later.

It must be noted, however, that Lauda and Stohr (1926) carried out a very extensive series of injections in over 50 children, in no case was a local lesion produced, although 3 of the injected children developed varicella; 3 other children, however, in contact with zoster, but not injected with vesicle fluid, also developed varicella They did not consider that their results demonstrated the infectivity of vesicle fluid derived from zoster lesions.

Animal experiments Lipschutz (1921 *b*) produced a reaction in the scarified corneas of 3 out of 7 rabbits inoculated with zoster fluid, and in 2 of these typical intranuclear inclusions were found Kin (1939 *a*) produced changes in the corneas and testes of rabbits, on inoculation with material from zoster vesicles, inclusions and EB's were found Lesions were produced by intracutaneous inoculation of this material in human beings (1939 *b*) Against this observation has to be set the opinion of a number of investigators that the disease cannot be transmitted to animals (e g, Marinesco, 1922 *a*, *b*, Blanc and Caminopetros, 1922, Marinesco and Draganesco, 1923, Doerr, 1925, Cole and Kuttner, 1925) It may be said that in these various experiments the following animals have been used rabbits, mice, monkeys, cats, sheep, pigeons, dogs, and guinea-pigs In view of these negative results the findings of Eckstein (1933–4) are of interest Eckstein injected monkeys intracerebrally with zoster vesicle fluid, and after 4 to 5 weeks they died with symptoms ir [illegible] perivascular infiltrati [illegible] and medulla. Seconda [illegible] aricella fluid (see p 2 [illegible] iatory changes in the monkey brain

Certain interesting results have been recorded in which, apparently, the virus of herpes febrilis has been isolated from typical zoster vesicles (Luger and Lauda, 1921, 1923–4, 1925, Cipolla, 1923–4, Becuwkes, 1939). The wide distribution of the herpes virus is so well recognized, however, that no particular stress should be laid on this finding

Morphology of the Virus

Elementary bodies of approximately 0 25 μ in diameter can be found in suitably stained films of vesicle fluid (Paschen, 1933, Amies, 1934, Taniguchi *et al*, 1934) These are most numerous 24 to 48 hours after the appearance of the lesion and can be agglutinated by zoster (and varicella) convalescent sera The EB's ap-

pear round, and measure 145 mμ by electron microscopy (Ruska, 1943). Inclusion bodies (already described) have been recorded with regularity only in human lesions, and their precise nature is uncertain. Kin (1940) claimed that his virus passed through a Berkefeld candle.

Cultivation

The virus was found to preserve its activity in tissue cultures of the Maitland type for 4 days, and local skin lesions were produced on intradermal injection of children (Glaubersohn and Barg, 1934). More definite evidence of propagation in tissue culture has not yet been published.

The virus has been found to produce characteristic pocks in the developing chorio-allantois of fertile eggs (Castro-Teixeira, 1936; Kin, 1940). Goodpasture and Anderson (1944) obtained fragments of human skin, infected them with vesicle fluid, and placed them on the chorio-allantois Acidophilic inclusions were found in the nuclei of hyperplastic epithelial cells. The chick membrane itself was not susceptible.

Effects of Physical and Chemical Agents

The virus retains its activity in glycerol in the refrigerator for at least 4 days (Glaubersohn and Barg, 1934).

IMMUNITY REACTIONS

Active Immunity

An attack of zoster is generally regarded as giving a life-long immunity against further recurrence, but such may occur. It is usually believed that varicella seldom occurs in cases that have had zoster, and vice versa, though after some years this cross immunity may disappear. It should be noted, however, that an investigation of schoolboys showed that about 71 per cent of boys with zoster had previously had chickenpox (Medical Research Council, 1938). This figure compared almost exactly with 67 per cent of controls who also had had chickenpox Clearly, these results do not support the view that chickenpox immunizes against zoster.

With regard to serological reactions, *complement fixation* reactions have been demonstrated by a number of authors using zoster antigen and patient's serum (Netter and Urbain, 1924 *a*, 1926, 1931, Netter *et al*, 1924, Bedson and Bland, 1929, Brain, 1933, Hasskó *et al*, 1938). The antigen for these tests consists of either vesicle fluid or dried crusts, the former being probably the best. The reaction is most powerful in the second week of illness, when up to 4 MHD of complement may be fixed Of more interest than this observation, however, has been the demonstration of cross fixation with material from cases of varicella With zoster vesicle fluid as antigen, equally good fixation was obtained in the presence of either zoster or varicella convalescent serum Corresponding results occurred if varicella crusts were used as antigen Zoster antigen does not fix complement in the presence of sera from patients suffering from herpes febrilis (Netter and Urbain, 1924 *b*) Fixation occurs between the sera of cases of arsenical or bismuth zoster and zoster antigen (Netter and Urbain, 1924 *c*) Despite the above positive findings, Thomsen (1934) was unable to demonstrate any fixation between zoster serum and zoster or varicella extract in a large series of cases (83), the converse reaction, with anti-varicella serum and zoster antigen, being also negative The study of Hasskó *et al.* (1938) also rather contradicted the older views Thus, although they found that zoster antigen and zoster serum fixed complement, there was only poor fixation by zoster serum and varicella antigen, or by varicella serum and zoster antigen

[illegible] These reactions were demonstrated with preparations of

[illegible] (Paschen, 1933, Amies, 1934) Zoster

of zoster elementary bodies, but zoster

serum agglutinated varicella elementary bodies to a somewhat lower titer than zoster elementary bodies.

Passive Immunity

*Zoster convalescent serum is said to protect exposed children against the de-*velopment of varicella (Kundratitz, 1925 *b*, Lipschutz and Kundratitz, 1925, Abramson, 1944) Such was not, however, the experience of Lauda and Stohr (1926) who found it devoid of any action in this respect Gundersen (1940) recommended the use of convalescent blood in treatment.

RELATIONSHIP BETWEEN ZOSTER AND VARICELLA

Clinical observations For many years clinical observers have suggested a relationship between zoster and varicella. Probably Bokay in 1888 (von Bokay, 1909) was the first to make the suggestion that zoster and varicella were very closely related, and he continued to support his original view in later publications (e g, 1919, 1924, 1928) Bokay attended numbers of cases where zoster had given rise to varicella in contacts. In certain cases varicella gave rise to zoster in contacts but *probably only one-tenth as commonly as the reverse. In these cases of contact* infection the usual incubation period is from 7 to 21 days, and over half the cases develop 14 to 16 days after exposure to infection

So many authors have published records of varicella occurring in contacts of zoster, and, much less commonly, vice versa, that we can mention only comparatively few by name (Low, 1919, Heard, 1921; Roxburgh, 1923; Roxburgh and Martin, 1926, Wilson and Mitchener-Little, 1926, Netter, 1928, who described 174 examples in France alone, Brain, 1931, Sayers, 1932; Bruusgaard, 1932, Robertson, [illegible] Weissmann-Netter and Lévy, 1938 [illegible] 1938) Thus, during the period of 5 years from 1930–4, 20 outbreaks of varicella were initiated by a case of zoster, the attack rate being 0 97 per cent When an epidemic of varicella was initiated by a case of varicella the attack rate was, however, 3 86 per cent

Varicella in contacts has been recorded after exposure to zoster occurring secondarily to arsenic therapy (Parkes Weber, 1946)

Experimental injections Experimental work performed in recent years has added weight to these clinical observations Thus, Kundratitz and other workers (*vide supra*) showed *that the injection of zoster vesicle fluid produced, in certain* cases, a typical varicellar eruption Kundratitz also noticed that such inoculations failed to "take" in children who had previously had an attack of varicella Further, children inoculated with zoster fluid were immune to later inoculations of varicella fluid

Study of the viruses As regards the two virus agents, neither has been studied very extensively, but sufficient has been learned to show their close relationship *Thus, similar types of elementary and inclusion bodies* have been found in the vesicles, and the histology of the vesicles is practically identical With regard to animals, zoster virus does not appear to be so readily transmissible as varicella It has been shown, however, that following intracerebral injection of zoster or varicella vesicle fluid rhesus monkeys may develop meningo-encephalitis (Eckstein, 1933–4)

Immunological observations Serological methods have yielded proof of the essentially close relationship between the two viruses Thus, as already mentioned, cross reactions between antisera and elementary bodies have been described by Amies, cross complement fixation has also been reported, but as already mentioned, both Thomsen and Hasskó failed to find any evidence of relationship by this latter

technique. With regard to virus neutralizing properties, the findings here are contrary to those obtained by other methods, for Rivers and Eldridge (1929 *b*) found that convalescent zoster serum mixed with varicella virus did not prevent the development of intranuclear inclusions on intratesticular injection of the mixture into monkeys (Rivers, 1926, 1927), whereas convalescent varicella serum and varicella virus did not cause the development of these inclusions

It is generally believed that zoster seldom develops in those who have had varicella, and vice versa. However, certain figures (M.R.C. Report, 1938) do not support this view (see also Ferriman, 1939, Crisp, 1940). Nevertheless, further proof should be adduced before one abandons the common belief that one of these diseases immunizes against the other.

Epidemiological observations. Bokay (1928) examined the incidence of both diseases in Budapest for 10 years (1915–24). He found a striking correspondence in the monthly prevalence of the two diseases, and the peak of the zoster curve regularly occurred a month before that of the varicella curve. Such, however, was not the experience of Rivers and Eldridge (1929 *a*), for with New York statistics they found the zoster figures to fall on a straight line, while the varicella figures were much higher from October to June than from June to September. Dahl (1946) found that the maximum incidence of chickenpox occurred in January-March, whereas that of zoster was usually in August, although sometimes from October to December. Cantor (1921) reported that, while zoster was quite common on the isolated Christmas Island, varicella was unknown. Wooley (1946) made similar observations on Tristan da Cunha, where some cases of zoster failed to give rise to any varicella, although the population had never suffered from this disease and must have been susceptible If the two viruses are closely related, it is admittedly difficult to explain these findings.

Conclusions

It may be said that on the basis of clinical observations and experimental work there is fairly strong evidence for postulating a close relationship between the 2 diseases. That is to say, zoster and chickenpox may be different manifestations of infection by one virus agent (Damm, 1931, Philadelphy and Haslhofer, 1934) It must be admitted that there are certain difficulties in the complete acceptance of this view, which is not held by all (Barrett, 1938).

In the first place, some of the experiments advanced in support of the close relationship of the 2 causal agents have failed to be confirmed by others, and secondly, why does varicella not give rise to zoster so commonly as zoster gives rise to varicella? It is possible that age may explain this, for zoster is commoner among adults and varicella among children (see Dahl, 1946) Thus children coming in contact with zoster are comparatively susceptible, the virus generalizes and causes an attack of varicella, whereas adults coming in contact with varicella are relatively immune, and either the virus produces no disease, or else an attack of zoster, which may be regarded as varicella occurring in a partially immune person That the strains of the causal agents themselves may behave somewhat differently is suggested by the report on school outbreaks already mentioned, in that the epidemics initiated by a case of zoster were much less infectious than those initiated by a varicella case

It is probably wisest, in conclusion, to regard the viruses of zoster and varicella as being closely related strains, the production of the individual syndrome being dependent both on the properties of the particular strain and the tissues of the host

CHAPTER XVII

HERPES FEBRILIS

HISTORICAL

A virus can be isolated from certain of the herpetic eruptions which is highly pathogenic for experimental animals, and has been studied intensively from this point of view Although herpes febrilis was probably first shown to be infective by Vidal (1873), little interest was taken by bacteriological workers until the end of World War I, when Gruter and Lowenstein reported that herpetic keratitis could be readily produced in rabbits. Soon afterwards, Doerr and his collaborators pointed out that extension of infection to the brain might occur in such animals For the next five years or so a large volume of work was carried out on the virus, mainly by Levaditi and his coworkers in France, and by the Swiss workers, Doerr and his colleagues During these years the chief concern was with the possible identity of the causal agent of herpes with strains isolated from cases of epidemic encephalitis by Levaditi and others Eventually it came to be realized that the two were in fact one and the same virus, although whether this is the cause of epidemic encephalitis in man is still undecided. It should be explained that the term "herpes" by itself refers to the various types of herpetic eruption (e g, febrile and simple) to be described in this chapter, it does not include herpes zoster. The causal agent of herpes is known as the herpes virus, the herpes febrilis virus, or the herpes simplex virus, all three terms are in common use and refer to the same agent.

CLINICAL FEATURES

Herpetic stomatitis It has been established that the common inflammatory condition of the mouth in children, known as aphthous stomatitis, is a manifestation of herpetic infection (Dodd, Johnston, and Buddingh, 1938, Gottron, 1938, Burnet and Lush, 1939 *b*, Burnet and Williams, 1939, Black, 1942, Scott, 1944, Buddingh, 1946, and others to be mentioned) This infection, which should be called acute herpetic stomatitis, is known by a score of other names, for example aphthous, Mikulicz's, Vincent's, or ulcerative stomatitis, acute infective gingivostomatitis, or periadenitis mucosa necrotica Vincent's fusospirochetes may be found in the lesions, but are only secondary invaders.

The diagnosis of these cases has been made by isolating the herpes virus by animal inoculation, and by testing acute and convalescent phase sera for virus neutralizing antibody. The latter tests have shown that herpetic stomatitis occurs in two forms In the primary form, most common in children aged 1 to 6 (newborn infants are resistant), there is a severe general febrile disturbance as well as the local stomatitis The gums are red and swollen Vesicles form on the tongue or buccal mucosa and quickly ulcerate There is oral fetor, and the regional glands are enlarged Lesions may occur also on the lips, face, and fingers The illness usually lasts 10 to 14 days Serological tests show absence of antibody in the acute phase, but its development to high titer during convalescence In this type of case the child is experiencing its first infection with the virus of herpes On recovery, the child is unlikely to develop such a severe illness again The virus persists, however, in the epithelial cells of the mouth or elsewhere, and gives rise to recurrent herpetic vesicles in the mouth or on the lips

In the recurrent form of stomatitis, there is a milder local lesion, without much general disturbance This type of stomatitis recurs throughout life, and sufferers constantly show a high level of virus neutralizing antibody

Primary herpetic stomatitis occurs characteristically in children, but may also

be noted in adults, it is probable that so-called herpetic fever is a primary oral infection (Scott, Steigman, and Convey, 1941). Trench mouth is probably also herpetic in origin. There is no evidence that Vincent's ulceration of the tonsil in adults is herpetic (Steigman and Scott, 1947)

Primary herpetic stomatitis may occur in small outbreaks in families, and is usually spread by an infected adult; the incubation period is about 3 to 5 days

Vaccination with calf lymph is said to benefit herpetic stomatitis (see, e.g, Woodburne, 1941).

Buddingh (1946) has described the syndrome of stomatitis and diarrhea of infants due to an apparently "new" virus, clinically the resemblance to herpetic stomatitis is close (see Ch XVIII).

Herpes febrilis This is the term applied to herpes arising in the course of a pyrexial disease. Thus it occurs commonly in pneumonia, malaria, influenza, and other febrile disorders The usual site is on the lip, when the term "herpes labialis" may be used Other parts of the face may also be involved by the eruption (herpes facialis). Herpetic vesicles are seldom bigger than a large pin-head and develop on a reddened base They are usually filled with clear fluid, but suppuration may occur The commonest site for herpetic vesicles is on the lips, inside and around the mouth, the cheeks, and the auricles

Herpes simplex This term is applied to herpetic eruptions unassociated with pyrexia, which may arise spontaneously, or secondarily to a variety of causes injections such as vaccines, milk, and colloidal metals (see Fischer, 1927, van Rooyen, Rhodes, and Ewing, 1941), ingestion of certain foodstuffs, or following gastric disorder. Herpes has been reported to follow the administration of a general anesthetic (Humphrey and McClelland, 1944) It occurs very commonly after artificial fever therapy, especially after the first exposure, it is less common after second and rare after third exposures (Warren, Carpenter, and Boak, 1940, Keddie, Rees, and Epstein, 1941)

Herpes genitalis Herpetic eruptions are not uncommon on the genitals, being found on the glans or body of the penis, and in the female, on the labia It is seldom that cases in the female are seen by the physician (Sharlit, 1940) Slavin and Gavett (1946 *a*) describe 3 cases of primary ulcerative vulvovaginitis in women

Herpes cornealis Herpetic infection of the cornea may assume a variety of forms, of which the dendritic ulcer is the best known (see Duke-Elder, 1938, Neame, 1942, Hamilton, 1943, Scott, 1944) The inflammatory reaction may be severe and result in serious scarring of the cornea It may be associated with a facial herpes Gallardo (1943) using serological tests, recognized dendritic ulcer to be the primary manifestation of herpetic infection in some cases, in others the infection was evidently recurrent or secondary

Recurrent herpes Certain persons are very susceptible to herpes, and why this should be is not clear It is probable that these people carry the virus in their saliva or elsewhere in the body, Burnet and others (see below) have suggested that in such cases the herpetic infection is contracted in infancy, as an aphthous stomatitis, and persists throughout life Some particular recurring susceptibility of the tissues may allow the virus to exert its pathogenic action from time to time Certainly, recurring genital herpes is most apt to occur in cases of irritation due to chronic gleet and prostatitis (Avit-Scott, 1931) In women recurrent herpes is often associated with the menstrual periods (Blum, 1926) A few cases have been described of recurrent herpes affecting an area of skin previously traumatized (see Findlay and MacCallum, 1940) These observers could not find the virus in the skin between attacks, and tentatively suggested it might remain latent in the spinal ganglia Investigation of this problem of recurrent herpes by means of repeated serological tests has not thrown any light on the matter (Hudson, Cook, and Adair, 1936)

Apart from the question of variations in the host as the predisposing factor in recurrent herpes, it is possible that the strain of virus itself may be one possessed

of unusual properties. Thus, Nicolau and Banciu (1924) inoculated a number of persons with strains of virus from cases of recurrent infection, and found that two of these developed recurrent herpes.

[illegible] gh herpes is usually regarded as a mild local [illegible] may arise from time to time. For example [illegible], 1926) describe *herpès nevralgique de Mauriac,* the symptoms being severe pains, crises of hyperesthesia in the perineum, tenesmus, sphincter spasm, and sciatica, all preceding the appearance of the eruption In less severe cases, herpes may be accompanied by pruritus, backache, and neuralgia. Doubtless these are due to the fact that the virus involves the corresponding gang- [illegible] (see Howard, [illegible]).

[illegible] len onset, rapid course, [illegible] fluid (see Abiteboul, 1936).

According to Janbon, Chaptal, and Labraque-Bordenave (1942), who give a number of references to French papers on herpetic meningitis, the condition may be recurrent; it may follow lumbar puncture, and may be observed as the only manifestation of herpetic infection. They state that meningo-encephalitis can be produced by intrathecal inoculation of the virus in human beings These authors isolated herpes virus from the CSF in one case of herpetic meningitis and refer to another positive result Armstrong (1943) also isolated virus from the CSF, and suggested that herpes may be the causal agent in some cases of "aseptic" meningitis.

Herpes virus has been regarded by some workers as the etiological agent in encephalitis lethargica. This question has not yet been settled, but most authorities are frankly skeptical (see Ch. XCI for a full discussion). Apart from the matter of encephalitis lethargica, there is no doubt that herpes virus may, on occasions, cause a severe and even fatal encephalitis or encephalomyelitis. Thus Warren, Carpenter, and Boak (1940) observed an encephalitis-like syndrome of short duration, and without sequelae, in a group of persons with severe herpes following fever therapy. Smith, Lennette, and Reames (1941) isolated herpes virus from the brain of a child of 4 weeks who died from encephalitis. Histological examination showed a meningo-encephalitis in the pons, medulla, and cerebellum, with areas of necrosis, perivascular cellular infiltration, focal and diffuse inflammation, and nerve cell degeneration with typical herpetic intranuclear inclusions. In another case, diagnosed clinically as equine encephalomyelitis, herpes virus was isolated, herpetic inclusions were found in profusion in glial cells and to lesser degree in neurones in the cerebrum (Zarafonetis *et al*, 1944). Two later cases have been described in young men by Whitman, Wall and Warren (1946). Herpes virus and herpetic inclusions were found in both cases The clinical picture was that of a severe encephalitis Histologically there was leptomeningitis over the cortex, perivascular cuffing in cerebrum, pons and medulla, and marked loss of ganglion cells in the cortex Herpetic inclusions were found in the astrocytes, in sections stained by phloxine-methylene blue. Fisher and Patrick (1947) have described another case.

The cases above described would appear to represent a true herpetic encephalitis, distinct clinically and histologically from encephalitis lethargica. The condition of inclusion encephalitis may here be recalled (see p 000) In this condition, of undetermined etiology, herpetic-type inclusions are found in the central nervous system

THE NATURAL HISTORY OF HERPETIC INFECTION

It has for long been recognized that herpes tends to be a chronic lifelong infection, and that recurrences are stimulated by various factors, especially fever. Burnet, on the basis of his own observations, and those of others referred to elsewhere in this chapter, has advanced the following conception of what he calls the

be noted in adults, it is probable that so-called herpetic fever is a primary oral infection (Scott, Steigman, and Convey, 1941). Trench mouth is probably also herpetic in origin There is no evidence that Vincent's ulceration of the tonsil in adults is herpetic (Steigman and Scott, 1947).

Primary herpetic stomatitis may occur in small outbreaks in families, and is usually spread by an infected adult; the incubation period is about 3 to 5 days

Vaccination with calf lymph is said to benefit herpetic stomatitis (see, e g, Woodburne, 1941).

Buddingh (1946) has described the syndrome of stomatitis and diarrhea of infants due to an apparently "new" virus; clinically the resemblance to herpetic stomatitis is close (see Ch XVIII)

Herpes febrilis This is the term applied to herpes arising in the course of a pyrexial disease. Thus it occurs commonly in pneumonia, malaria, influenza, and other febrile disorders The usual site is on the lip, when the term "herpes labialis" may be used Other parts of the face may also be involved by the eruption (herpes facialis). Herpetic vesicles are seldom bigger than a large pin-head and develop on a reddened base They are usually filled with clear fluid, but suppuration may occur The commonest site for herpetic vesicles is on the lips, inside and around the mouth, the cheeks, and the auricles.

Herpes simplex. This term is applied to herpetic eruptions unassociated with pyrexia, which may arise spontaneously, or secondarily to a variety of causes injections such as vaccines, milk, and colloidal metals (see Fischer, 1927, van Rooyen, Rhodes, and Ewing, 1941), ingestion of certain foodstuffs, or following gastric disorder. Herpes has been reported to follow the administration of a general anesthetic (Humphrey and McClelland, 1944). It occurs very commonly after artificial fever therapy, especially after the first exposure, it is less common after second and rare after third exposures (Warren, Carpenter, and Boak, 1940, Keddie, Rees, and Epstein, 1941)

Herpes genitalis Herpetic eruptions are not uncommon on the genitals, being found on the glans or body of the penis, and in the female, on the labia. It is seldom that cases in the female are seen by the physician (Sharlit, 1940). Slavin and Gavett (1946 *a*) describe 3 cases of primary ulcerative vulvovaginitis in women.

Herpes cornealis Herpetic infection of the cornea may assume a variety of forms, of which the dendritic ulcer is the best known (see Duke-Elder, 1938, Neame, 1942, Hamilton, 1943, Scott, 1944) The inflammatory reaction may be severe and result in serious scarring of the cornea It may be associated with a facial herpes Gallardo (1943) using serological tests, recognized dendritic ulcer to be the primary manifestation of herpetic infection in some cases, in others the infection was evidently recurrent or secondary.

Recurrent herpes Certain persons are very susceptible to herpes, and why this should be is not clear It is probable that these people carry the virus in their saliva or elsewhere in the body, Burnet and others (see below) have suggested that in such cases the herpetic infection is c
and persists throughout life Some p
may allow the virus to exert its pa
recurring genital herpes is most apt to occur in cases of irritation due to chronic gleet and prostatitis (Avit-Scott, 1931) In women recurrent herpes is often associated with the menstrual periods (Blum, 1926) A few cases have been described of recurrent herpes affecting an area of skin previously traumatized (see Findlay and MacCallum, 1940) These observers could not find the virus in the skin between attacks, and tentatively suggested it might remain latent in the spinal ganglia Investigation of this problem of recurrent herpes by means of repeated serological tests has not thrown any light on the matter (Hudson, Cook, and Adair, 1936)

Apart from the question of variations in the host as the predisposing factor in recurrent herpes, it is possible that the strain of virus itself may be one possessed

6 Herpes occurring symptomatically in such varied diseases as cerebrospinal meningitis, pneumonia, diphtheria, influenza, catarrhal jaundice, erythemata, and secondary syphilis yields a virus with the same characteristics as that obtained from cases of primary herpes (Teissier *et al*, 1922 *a*).

7. Herpetic stomatitis yields a virus identifiable as that of herpes by its biological properties A specific serological response occurs in primary infections (see above).

8. Intranuclear inclusion bodies, indistinguishable from one another, have been reported in human herpes febrilis, cornealis, and genitalis, and in experimental lesions in animals (Lipschütz, 1921 *a*, *b*, *c*, Fuchs, see 1933).

THE DISTRIBUTION OF VIRUS IN INFECTED AND HEALTHY PERSONS

1. *Herpetic vesicle*. The virus is abundantly present in the vesicular stage, but when the crust forms all virus has disappeared (Teissier, Gastinel, and Reilly, 1926 *a*).

2. *Blood*. The virus may be found in the blood of persons suffering from herpetic eruptions, although this is probably rare (Löwenstein, 1919, Bastaï and Busacca, 1924 *b*), and has, in fact, been denied altogether (Teissier, Gastinel, and Reilly, 1926 *a*, *b*).

3.

fluid o

in one

patient with no herpetic eruption. This is an important observation and indicates that the virus may, although rarely, be found in the cerebrospinal fluid of patients who, at the moment, do not suffer from herpes. Zurukzoglu (1937) has also isolated two strains of herpes virus from the cerebrospinal fluid of healthy persons.

With regard to the cerebrospinal fluid of herpetic patients, the consensus of opinion is that the virus may be found on occasions (Ravaut and Rabeau, 1921; Bastaï and Busacca, 1924 *a*, Zurukzoglu, 1937). It should be added, however, that a number of competent investigators have been quite unable to detect its presence (e g, Doerr and Zdansky, 1924, Levaditi, 1925, Teissier, Gastinel, and Reilly, 1926 *a*, *b*).

As already described, the virus has been isolated on a few occasions from the CSF and brain of cases of herpetic meningitis and encephalitis

4 *Saliva* Herpes virus has been found in the healthy saliva by a number of workers (e.g, Levaditi, Harvier, and Nicolau, 1921; Doerr and Schnabel, 1921 *a*, Teissier, Gastinel, and Reilly, 1926 *b*) The virus is attached to the salivary epithelial cells and is probably associated with the buccal mucus, as preparations of the salivary glands themselves are avirulent (Levaditi, Harvier, and Nicolau, 1921). The presence of the virus has usually been detected by its power of producing keratitis in rabbits Levaditi and his collaborators have stated that 80 per cent of normal specimens of saliva produce experimental keratitis, but only in 15 per cent. is this keratitis severe enough to be followed by cerebral involvement (*vide infra*). These high figures have not, however, been generally accepted by other workers, who have quite failed to find any virus in normal saliva (e g, Flexner and Amoss, 1925 *c*) Nevertheless there seems no doubt that the virus can on occasions be found in this site

Several workers have investigated the saliva of persons suffering from herpes and have, though rarely, been successful in demonstrating the presence of the virus (e g, Isaicu and Telia, 1922, Flexner and Amoss, 1925 *c*, Nicolau and Poincloux, 1922, 1924) Thus, it has been found in the saliva of patients suffering from labial and facial herpes and herpes of the finger The saliva of persons predisposed to herpetic eruptions contains the virus more frequently than that of other persons, and it may be found in the intervals between attacks (Levaditi, 1926).

"natural history" of herpes (Burnet and Lush, 1939 *b*, Burnet, Lush, and Jackson, 1939 *a*; Burnet and Williams, 1939, Burnet, 1945).

Herpetic infection usually occurs in childhood, often taking the form of an herpetic stomatitis. The virus tends to persist throughout life as a latent infection, giving rise to recurrent herpes of the mouth, lips, genitals, or elsewhere, on appropriate stimulation Primary infection may, however, occur on the skin, vulva, or eye, and may be delayed till adult life (see also Gallardo, 1943; Nagler, 1946, Slavin and Gavett, 1946 *a*).

This concept was formulated on the results of serological tests, as well as skin tests performed by Nagler (1944). Thus, Burnet and Williams found that the sera of most young children contained no antibody, while the sera of most adults gave a positive reaction (see also p. 189). The sera of children with herpetic stomatitis showed no antibody at the time of the illness, but developed it later. Persons with a history of herpes showed virus neutralizing antibody, and reacted to a virus reagent introduced intradermally (Nagler, 1944, 1946). Persons without a history of herpes showed no antibody. When antibody occurred in children's sera it was present to the same high titer as adults. Sera showing a small amount of antibody were seldom found, it being either absent, or present to high titer. Burnet found some evidence that the poorer type of patient was more frequently infected with herpes than one coming from a better house (see also Andrewes and Carmichael, 1930) He concluded that the average public hospital Australian patient was primarily infected between the ages of 1 and 5, and developed stomatitis, the virus persisting throughout life.

RELATIONSHIP TO OTHER SKIN DISEASES

It has been suggested that erythema multiforme is very commonly preceded by herpes (Urbach, 1945)

It appears that certain cases of the skin disease known as Kaposi's varicelliform eruption (see Ch. XXVII), are caused by the virus of herpes (Wenner, 1944, Anderson, 1945, Lynch, 1945, Jaquette, Convey, and Pillsbury, 1946). Wenner isolated the virus from the brain of one case, although it had caused no cerebral signs or lesions A mild and a severe type of herpetic Kaposi's eruption have been described, and the term "systemic herpes" has been used (Barker and Hallinger, 1947). Other reports of isolation of virus from Kaposi's eruption are those of Ruchman, Welsh, and Dodd (1947), and Kipping and Downie (1948)

THE COMMON ETIOLOGY OF HERPETIC ERUPTIONS

To-day all herpetic eruptions (always excepting, of course, those of zoster) are thought to be due to one and the same virus The evidence on which this opinion is based will now be detailed

1. Vesicle fluid from all varieties of herpetic eruption can be inoculated into the human skin with consequent production of a typical crop of "simplex" vesicles (Vidal, 1873, Lipschutz, 1921 *b*, Teissier, Gastinel, and Reilly, 1922 *c*, Frei, 1931, Zurukzoglu and Hruszek, 1933)

2. Vesicle fluid from herpes febrilis produces a keratitis when applied to the rabbit's eye (Lowenstein, 1919, 1920, Gruter, 1920)

3 Herpes cornealis yields a virus with the same characteristic action in animals (Doerr, 1920, Doerr and Vochting, 1920, Luger and Lauda, 1921 *a*)

4 Herpes labialis yields the same virus, which will produce typical herpes cornealis when suitably applied to the human cornea (Doerr, 1920, Doerr and Vochting, 1920, Fuchs, 1921, and see 1933)

5. Vesicle fluid from herpes genitalis also produces keratitis in the rabbit, and man can be reinfected with material taken therefrom (Fontana, 1921, Blanc and Caminopetros, 1921 *c*)

investigated the possible rôle of *Aedes aegypti* as an insect vector, and although unable to come to a definite decision, their work strongly indicated that the strains used had been transmitted thereby.

LABORATORY DIAGNOSIS OF HERPES

Virus can be sought in vesicle fluid, saliva, corneal secretion, or brain suspension When working with brain suspension, it may be advisable to inoculate varying dilutions, as concentrated material may not infect so readily (Fisher and Patrick, 1947).

Films may be stained by Paschen's or other method (see Ch III) and examined for elementary bodies Of more value than this, however, is animal experiment, the simplest procedure being to drop some of the vesicle fluid upon the scarified cornea of a rabbit, and watch for the development of keratitis. If sufficient fluid is available, a rabbit may, in addition, be injected intracerebrally (*vide infra*). If the rabbit does not succumb, its serum should be tested for antibody, as an inapparent infection may have resulted (see Evans, Bolin, and Steves, 1945). Mice, guinea-pigs, and hamsters can also be inoculated intracerebrally and intraperitoneally; the convalescent serum should be tested for antibody (Zarafonetis *et al*, 1944, Evans, Bolin, and Steves, 1945; Whitman, Wall, and Warren, 1946).

A rise in antibody, most readily detected by the neutralization of infectivity for mice or the chorio-allantois, occurs in convalescence from a primary infection. In cases of recurrent herpes, however, it will be difficult to detect an antibody increase owing to the initial high level

PROPERTIES OF STRAINS OF DIFFERENT ORIGIN

Various tests can be adopted in the analysis of herpes virus strains By the use of human and rabbit sera, Slavin and Gavett (1946 *b*) were able to differentiate antigenically between a strain LH isolated from vulvovaginitis and the animal-passed HF strain. Florman and Trader (1947) investigated 3 recent human strains and 1 passed in animals (probably HF) They used corneal challenge experiments in immunized rabbits, and inoculation of mice or the chorio-allantois with virus-serum mixtures, the latter was found the most sensitive, some strain differences could be detected They found that two strains isolated from human nervous disease were not more neurotropic in laboratory animals than a strain isolated from the mouth The mouth strain was as dermotropic on inoculation in the guinea-pig skin as was a strain isolated from nerve tissue. It is evident that herpes virus is pantropic, and the tendency to dermotropic or neurotropic characters depends on the host and not the virus; a strain neurotropic in one host may not show this tendency in another

ANIMAL INOCULATION WITH HERPES VIRUS

A. Rabbits

Routes of injection.

These animals can be infected by a variety of routes

1. *Corneal inoculation*

Following observations of Gruter (1920), Lowenstein (1919, 1920) published the results of corneal inoculation of the rabbit with the contents of herpes febrilis vesicles. He found that a severe keratitis developed and that the infection was transmissible to other rabbits, this observation has been abundantly confirmed After such inoculation the cornea becomes "steamy" in about 10 hours, small vesicles form later, and there is usually an associated conjunctivitis Epithelial cells in the exudate contain small granular inclusions (Blanc and Caminopetros, 1921 *a*).

The virus can be found quite readily in the saliva in cases of herpetic stomatitis (see above).

5. *Conjunctival sac.* The virus can apparently be carried in a more or less inactive condition in the conjunctival sac, but if the cornea is injured, then it may produce keratitis (Grüter, 1924, Busacca, 1925). It may also cause severe unilateral conjunctivitis, developing without obvious cause (Granstrom, 1937).

6 *Other skin lesions.* The virus of herpes has been recovered on rare occasions from zoster vesicles (see p. 161), sycosis pustules (Naegeli and Zurukzoglu, 1935).

HISTOLOGY

(*a*) *The vesicle.* The histology of the herpetic vesicle is similar whatever its site, and was accurately described by Unna in 1896 The vesicle is thick-walled, and arising immediately superficial to a swollen papillary process, is entirely subepithelial in position. The cavity of the vesicle is filled with a fibrinous network and prickle cell debris, while the wall is composed of altered prickle cells showing coagulation necrosis. The most superficial layers of the wall are composed of vesicular cells from which the nuclei have largely disappeared. Superficial to the blister is a layer of almost unaltered prickle cells corresponding to the normal middle layer. The whole lesion is covered over by a thick layer of cells merging at the sides into the granular and superficial prickle cell layers. These cells show coagulation necrosis, the nuclei are pale in color and shadowy in appearance, while the cytoplasm is transformed into a fibrinoid mass. In the vicinity of the vesicle there is some edema of the prickle cell layer and considerable swelling and some congestion of the cutis Healing takes place by a deepening of the process of cornification, and a marked infiltration of polymorphs into the site of the vesicle and surrounding parts.

The lesion of herpes is thus seen to consist of a fibrinous inflammation of the epidermis, which tissue becomes detached, overlying a swollen papilla. The characteristic vesicle forms in the space thus provided between the papillary process and the inflamed epidermis. The vesicle fluid contains polymorphs, large mononuclears, and large epithelial cells sometimes showing in their cytoplasm "minute bodies," staining basophilic and similar to those found in the various experimental lesions of herpes (Da Fano, 1923).

Inclusion bodies were first described by Lipschutz (1921 *a, b, c*) in the lesions of herpes genitalis and febrilis, and occur in the nuclei of those epithelial cells superficial to the vesicle. They are granular, eosinophilic, and measure from 2 μ up to the diameter of the nucleus itself. Lipschutz holds these bodies to represent the virus itself, while Luger and Lauda (1921 *c*) among others believe that they are only products of degeneration (for further details, *vide infra*)

(*b*) *Root ganglia* Howard (1905) demonstrated inflammatory infiltration with polymorphs, and degenerative changes in the corresponding gasserian ganglion in cases of herpes occurring in meningitis and pneumonia.

(*c*) *Cornea.* The changes are those of partial epithelial necrosis and infiltration of the substantia propria with leukocytes Epithelial cells may show typical intranuclear inclusions (Fuchs, see 1933).

TRANSMISSION OF HERPES

From what has been said concerning the distribution of the virus, it will be evident that herpes may be spread by saliva or droplets of oral secretion Primary infection may be contracted directly by kissing, or indirectly, by using infected cups, spoons, and other fomites Infection is most readily transmitted in childhood and the skin and mucous membranes of the young child are probably highly susceptible (Burnet, 1945) Genital herpes is spread by sexual intercourse (Hruszek, 1937, Slavin and Gavett, 1946 *a*), as proved experimentally in the case of the rabbit by Levaditi and Nicolau (1923 *a*). Simmons, Kelser, and Cornell (1933, 1934)

and then right itself only to fall to the other side immediately. Trismus, nystagmus, and excessive salivation may all be found. Excessive lacrimation is a rare symptom (Flexner and Amoss, 1925 *c*). Finally the animal dies quietly with limbs extended. The pathogenesis and pathology of herpetic encephalitis are described below.

"Fixed" virus With intracranial passage the virus becomes exalted in virulence and eventually "fixed," when it shows little cutaneous affinity (Blanc and Caminopetros, 1921 *b*, Le Fèvre de Arric, 1922 *a, b, c*). Such a virus has a very short incubation period and usually kills within 3 days, all the symptoms being greatly exaggerated A well-known strain is the HF of the Rockefeller Institute.

Chronic herpetic encephalitis. Sometimes, after intracranial injection, a chronic type of encephalitis may develop (Da Fano and Perdrau, 1927). This reaction is produced most readily in partially immunized rabbits, but sometimes occurs after primary injections of virus, if the incubation period is prolonged The rabbits suffer from an attack of encephalitis as above described but, while some recover, the majority remain in a semilethargic condition

3 *Intravenous injection*

A number of effects have been reported following injection of rabbits by this route Thus encephalitis and a generalized herpetic eruption were recorded by Doerr and Voechting (1920). Encephalitis is not, however, generally produced unless the brain is first mildly injured, e g, by a gentle knock on the head, or by injection of substances such as urotropine and sodium salicylate which appear in [illegible]

Smith (1931 *a, b*), who also found that these lesions were prevented by immune serum

Myelitis of the lumbar cord may follow intravenous injection, virus reaching that site very quickly and before it can be demonstrated in higher parts of the cord The infection may remain localized to the lumbar region, producing paraplegia, or may ascend in the central nervous system (Koppisch, 1935, Doerr and Hallauer, 1936, Hoff and Potzl, 1937).

Cooke, Hurst, and Swan (1942) found that virus could first be detected in the viscera, where necrotic changes subsequently developed Later, lesions were found in the spinal ganglia and dorsal cord at approximately the same time, finally lesions were found in other parts of the CNS Occasionally the olfactory bulbs might be infective before other regions of the cerebrum Young rabbits usually showed signs sooner than older animals The intracarotid injection of virus in sufficient concentration gave rise to primary encephalitis or myelitis in equal numbers of rabbits The addition of a suspension of toadstool spores in 1 per cent. gelatin, or of mayonnaise, to a concentration of virus, usually noninfective, led almost always to a primary encephalitis, if infection developed.

4 *Dermal inoculation*

This method of inoculation results in a crop of herpetic vesicles in 5 to 7 days. Pustulation may occur before the lesions finally crust over If the skin is tarred prior to inoculation, vesicles develop in 3 to 4 days and are distributed like zoster lesions, the animal frequently succumbs, and the corresponding spinal ganglia contain the virus (Teague and Goodpasture, 1923, 1923–4) Paralytic and trophic lesions may follow injection of the skin of a pad (Teissier, Gastinel, and Reilly, 1929) Flexner (1928 *a*) found that following intradermal injection myelitis occurred with, later, extension to the brain, the lumbar cord contained more virus than the pons

Keratoconjunctivitis may follow the dropping or swabbing of vesicle fluid on to the cornea without scarification (*Gallardo, 1943*).

Soon after Lowenstein's important discovery it was pointed out that nervous symptoms sometimes developed in rabbits with herpetic keratitis (Doerr, 1920, Doerr and Vochting, 1920). These rabbits showed excessive salivation, pyrexia, incoordination, convulsions, trismus and gnashing of teeth, and paresis, all of which indicated an encephalitic process. Death usually occurred in 8 to 15 days, although some survived for much longer. Strains of virus isolated from recurrent herpes are said to produce cerebral involvement (after corneal inoculation) much less commonly than do strains from primary infections (*Lépine and Schoen, 1931*).

Histology of herpetic keratitis The changes are those of an acute inflammatory reaction with considerable congestion of the substantia propria, accompanied by polymorphonuclear infiltration. Main interest centers, however, in the presence of inclusion bodies. These were first described by Lipschutz (1921 *c*) who claimed them to be aggregates of virus These bodies appear even within 7 hours and attain their maximum size within 24 hours, after which they become smaller. They are round or oval structures with a definite edge, being found within the nuclei, usually in the epithelial cells, but less commonly in the fibroblasts. They are eosinophilic and somewhat granular, a clear zone separates them from the hyperchromatic nuclear membrane. Similar bodies have been found by Goodpasture and Teague (1923–4 *a*) who agree with Lipschutz that the finding of these bodies definitely indicates the presence of the virus. Others have observed similar bodies, but believe them to be of degenerate nature (e g, Luger and Lauda, 1921 *a*), the latest work (*vide infra*) supports Lipschutz's original view.

With regard to the cytoplasm, "minute bodies" which are small basophilic granules have been described in epithelial cells by Cowdry and Nicholson (1923) who, however, draw attention to a close resemblance between these and the "Russell bodies" normally found in plasma cells (see Dubreuil and Favre, 1914).

Nicolau (*vida infra*) has described small inclusion bodies which occur in the nuclei and cytoplasm of the cells of the cornea. These bodies are granular and with the progress of the infection fuse to form the larger "Lipschutz" type of body. They closely resemble the bodies described by Da Fano and probably represent the etiological agent

2 *Intracranial injection*

Subdural or intracerebral injection produces an encephalitis, fatal in about 5 days and transmissible to other rabbits, as shown first by Blanc (1921) Under certain conditions a chronic type of encephalitis may develop On occasions intracranial injection may give rise, not to the usual encephalitis, but to a primary myelitis (Doerr and Hallauer, 1936) After repeated cerebral passage, the virus loses some of its affinity for the cornea and does not regularly produce keratitis (Perdrau, 1925) After intracerebral injection of rabbits, the usual incubation period is reduced by 2 days if a second injection (intradermal or intracerebral) is given 48 hours after the original, i e, the second injection has an "aggressin-like" action (Perdrau, 1925)

On intracisternal injection herpes virus tends to produce a meningo-encephalitis, usually acute and fatal, but sometimes chronic and recoverable (Janbon, Chaptal, and Labraque-Bordenave, 1942)

Features of acute herpetic encephalitis Blanc and Caminopetros (1921 *b*) gave one of the first descriptions of this syndrome Following an incubation period of some 4 to 6 days, the animal becomes ill, the temperature rises and remains raised until it falls with the first appearance of symptoms about 2 days later The symptoms are indicative of cerebral irritation, the animal moves about by fits and starts, stopping very suddenly, frequently turns the head round, and breathes irregularly The fore-paws are often lifted and show tremor, the animal may fall to one side,

Pathogenesis of herpetic encephalitis in the rabbit.

Following direct intracranial injection, rabbits die of herpetic encephalitis, moreover when an animal dies of herpetic infection following injection by other routes, it is also found to present evidences of involvement of the central nervous system.

It was at first thought that when encephalitis followed a peripheral lesion such as keratitis the infection spread by the blood stream, because Doerr and Vochting (1920) were able to produce encephalitis by intravenous injection. Levaditi (1922) claimed, however, that the virus spread from the cornea by the retina and optic nerve. The extensive work of Goodpasture and Teague (1922–3, 1923–4 *b*) has also shown that the virus usually spreads to the brain from peripheral lesions by the nerves and not by the blood (see also Nicolau, Dimancesco-Nicolau, and Galloway, 1929) In the case of the cornea, for instance, the virus spreads by infecting the axis cylinders of the branches of the fifth cranial nerve, and the first intracranial lesion produced is in that part of the pons and medulla corresponding to the central connection of this nerve. Goodpasture and Teague further showed that the virus can spread to the brain along the vagus, following injection of the tracheal mucosa, along motor nerves after injection of the masseter, and along sympathetic nerves after intrahepatic inoculation In all these cases the first parts of the brain to be affected are those corresponding to the central connections of the affected nerves

It is possible that corneally inoculated virus may pass to the olfactory mucosa by the nasolacrimal duct, and thence invade the brain via the olfactory bulbs (Gaviati, 1922)

Goodpasture (1925 *a*) has shown that when herpetic encephalitis develops in rabbits after contact with infected animals the virus reaches the central nervous system through the sensory divisions of the fifth and ninth nerves Further, histological changes are first noted in association with the central nuclei of these nerves He has inferred, therefore, that in these cases the portal of entry is by the mucosa of the mouth, nose, or throat.

McClellan and Goodpasture (1924) employed an ingenious method for detecting the site of damage in these various experiments. They injected trypan blue intravenously just before death, immediately after death the brain was fixed by intracarotid injection of formalin and was prepared by Spalteholz's method The affected area of the brain appeared bright blue

Marinesco and Draganesco (1932) have also published studies which strongly support the theory that the virus reaches the central nervous system by the nerve tracts, for after corneal inoculation they found the first lesions to develop around the central connections of the fifth nerve, the reaction being meningeal and most marked on the inoculated side Examination of the bulb showed a destruction of the nerve fibers in the descending trigeminal root.

After nasal instillation these authors recorded lesions in the olfactory bulbs, and changes in Ammon's horn They also injected the vagosympathetic trunk, obtaining central lesions in the dorsal vagus nucleus, descending root of the trigeminal, and spinocerebellar fibers Inoculations were also made into the facial nerve, and into the masseter muscle, following this the gasserian ganglion showed intense infiltrative changes and lesions of the central nervous system were also found After intrasciatic injection lesions were produced in the nerve and the cord (mainly on the inoculated side), these were inflammatory and took the form of interstitial neuritis and ganglioradiculitis With the progress of the infection lesions were also found in the cord and bulb

Two further experiments by these workers may be quoted to emphasize the experimental basis for believing that herpes virus spreads by the nerves After transection of a sciatic nerve, injection of the distal portion produced no encepha-

5. Other routes.

Nasal instillation secures infection, and virus spreads by the trigeminal nerves (Gordon, 1928).

Rabbits can be infected subcutaneously and by intramuscular injections. Injection into the anterior chamber also gives positive results, as do injections by the following routes: trachea, conjunctiva, retina, buccal mucosa, ovary, or testicle (Goodpasture and Teague, 1923–4 *a*); external ear (Vieuchange, 1936); prepuce or vagina (Levaditi and Nicolau, 1923 *a*), and sciatic nerve (Pette, 1926, Teissier, Gastinel, and Reilly, 1929). Rabbits are susceptible to contact infection from cases of herpetic keratitis (Goodpasture, 1925 *a*).

Blood changes in infected rabbits. There is a polymorphonuclear leukocytosis with relative lymphopenia, and the count may rise to 17,000 or even 25,000 per c.mm Red cells are not affected (Le Fèvre de Arric, 1923; Remlinger and Bailly, 1926 *b*).

The distribution of virus in the infected rabbit.

The ocular secretion, after corneal inoculation, may contain the virus for as long as 7 days, and it can be most readily recovered from the nictitating membrane (Scott, Steigman, and Convey, 1941).

The blood may sometimes contain the virus (Luger, Lauda, and Silverstern, 1921, Greenbaum and Harkins, 1925, Remlinger and Bailly, 1926 *b*, Gildemeister and Heuer, 1929).

The cerebrospinal fluid is frequently virulent (Urbain and Schaefer, 1927, Flexner and Amoss, 1925 *c*; Gildemeister and Watanabe, 1930–1) Flexner and Amoss have shown that the virus is most frequently found in the cerebrospinal fluid in cases where meningitis is a prominent feature, such as after intracranial injection of unfiltered virus-containing material From 1 to 3 days after inoculation by this route the virus may be found in the cerebrospinal fluid It then seems to disappear for a short time only to reappear, concurrently with pleocytosis, from the fifth to sixth day onwards (Nicolau and Kopciowska, 1931).

The central nervous system Virus can usually be recovered with ease from the brain of rabbits dying of acute herpetic encephalitis, especially after glycerolization In animals dead from chronic herpetic encephalitis, treatment of the brain with glycerol or alumina may be needed to "unmask" the virus (Da Fano and Perdrau, 1927, Perdrau, 1938). Perdrau (1938) found that virus could be recovered directly from the brains of rabbits which developed encephalitis 6 months after active immunization with living virus Good (1947) recovered virus after 9 months from the brain of a rabbit that developed an acute illness on 3 occasions, induced by anaphylactic shock

French authors have described the condition of autosterilizing neuroinfection, certain rabbits injected with strains of herpes die, apparently from encephalitis, but no virus can be isolated from their brains (see Lépine and Schoen, 1931) It is claimed that the reaction of the tissues has destroyed the virus This question is further discussed in the chapter on encephalitis lethargica (Ch XCII)

Peripheral nerves After intracranial injection the virus may be found in the peripheral nerves in a certain percentage of cases (Nicolau and Dimancesco-Nicolau, 1928, Nicolau, Dimancesco-Nicolau, and Galloway, 1929, Kopciowska and Stroian, 1929).

Secretions The saliva and nasal secretion may harbor the virus (Perdrau, 1925, Urbain and Schaefer, 1927), as may the urine and feces (Flexner and Amoss, 1925 *c*, Urbain and Schaefer, 1927)

Viscera The spleen and suprarenal may contain the virus (Luger, Lauda, and Silverstern, 1921, Urbain and Schaefer, 1927) The following organs do not contain virus lung, kidney, ovary, testes, striped muscle, and skin (Urbain and Schaefer, 1927)

as well as lying free. They are stained black by osmic acid, give a positive MacCallum test for masked iron, and are almost certainly nuclear in origin (Cowdry and Nicholson, 1923). Indeed they resemble rather closely the Gamna-Favre bodies of lymphogranuloma inguinale.

3. "Minute bodies" measure 0 3 μ to 0 5 μ in their longest diameter and are either bacillary or coccal in shape. They are found in the cytoplasm of neuroglial cells and macrophages but may also lie free. These bodies do not react to Mac-
...dria (Cowdry
...l by Da Fano
...alitis (1921).
...ose described
...and nucleus
of nerve and glial cells, also sometimes in vascular endothelial and mononuclear cells

Chronic lesions. Da Fano and Perdrau (1927) obtained a chronic meningo-encephalitis in partially immunized rabbits The animals developed a typical herpetic syndrome from which they recovered, either completely or with lethargic and apathetic symptoms. The histological findings were as follows: widespread chronic cellular infiltration, extensive destruction of nerve cells; true- and pseudo-calcification, and formation of young scar tissue. The brains of such rabbits were not infective on removal but became so after preservation in glycerol Perdrau (1938) found that alumina would also activate virus. Histologically, such changes resembled those of human encephalitis more than did the acuter lesions.

(*b*) *Following injection by other routes.*

The appearances of encephalitis following corneal and dermal inoculation are similar to those just described, except that the meningeal changes are usually less marked The lesions are usually most pronounced in the area corresponding to the central connections of the nerve supply to the site of inoculation, as has been emphasized by Goodpasture and Teague, and by Marinesco and Draganesco. When virus is injected intravenously, the lesions are diffuse from the start.

(*c*) *Other factors governing the histological appearances.*

1 The meningeal reaction is more evident with an inoculum of unfiltered brain tissue than with a Berkefeld filtrate (Flexner and Amoss, 1925 *c*).

2. The virulence of the strain also plays a part Animals injected with a strain of herpes virulent for nervous tissue show the characteristic reaction above described Animals injected, however, with a strain relatively avirulent for nervous tissue show a much more chronic type of reaction, the meningitis is mainly mononuclear, parenchymatous changes being slight and mainly restricted to perivascular cuffing (Le Fèvre de Arric, 1922 *b*, Flexner and Amoss, 1925 *c*; Goodpasture, 1925 *b*).

3 Attention must here be drawn to the description given by McCartney (1924) and others that in a proportion of stock animals, prior to intracerebral injection altogether, may be found perivascular and subependymal mononuclear infiltrations due to *Encephalitozoon cuniculi* It would appear, therefore, as though the description of certain authors, particularly with regard to the more chronic lesions (e g, Le Fèvre de Arric, 1922 *b*, Flexner and Amoss, 1925 *c*), should be accepted with some reserve

4 Very young rabbits are said to be strongly resistant to herpetic encephalitis (Goodpasture, 1925 *b*).

B. Guinea-pigs

1. *Corneal inoculation* with rabbit-passed virus produces keratitis (Doerr and Vochting, 1920, Blanc and Caminopetros, 1921 *a*), but spread to the brain apparently does not occur (Doerr and Schnabel, 1921 *b*)

litis. If, however, the nerve was crushed, and an injection made below the site, then infection eventuated. As the authors stated that the nerve fibers were destroyed by crushing, they claimed that the infective agent must have traveled centripetally in the interstitial spaces, and not along the axis cylinders Further, as meningitis is such a noticeable feature of herpetic nervous lesions, it is suggested that the virus travels in the interstitial and perineural lymphatics to reach the cerebrospinal fluid and thus penetrate to the nervous parenchyma.

Levaditi and his coworkers have investigated the fate of virus instilled nasally. They found that it usually spreads by the trigeminal route, and can first be detected in the gasserian ganglion. Although lesions may be found in the olfactory bulbs, this cannot be an important source of spread, for surgical extirpation fails to prevent encephalitis (Levaditi and Haber, 1935; Levaditi, Hornus, and Haber, 1935).

Whether the virus spreads by the axis cylinders or by perineural lymphatics is not known, but nerves are evidently the important pathways of infection Blood-spread may, however, play some part, for intravenous injection may give rise to herpetic encephalitis or myelitis, the former especially after cerebral trauma It may be mentioned that in one of Marinesco and Draganesco's experiments virus was injected into the peripheral extremity of a cut sciatic nerve Contrary to expectation, herpetic encephalitis developed, almost certainly due to blood-spread

The histology of herpetic encephalitis in the rabbit.

(*a*) *Following intracranial injection.*

Acute lesions. Within 24 hours of injection changes are found in the neighborhood of the needle track, where there is hemorrhage. An edematous area in which the vessels show cuffing with polymorphs, some lymphocytes and plasma cells, surrounds this hemorrhage Some basal hemorrhages are also found. With the progress of the infection the following changes occur. The meninges, mainly those of the base, show considerable infiltration with polymorphs, small lymphocytes, large mononuclears, and plasma cells, and even at an early stage many of the polymorphs are necrotic, there is also proliferation of the fixed cells of the meninges The vessels penetrating the brain show perivascular cuffing with cells similar to those infiltrating the meninges, and there is hypertrophy and multiplication of the lining endothelium The adventitial cells also proliferate, while the parenchyma of the brain shows some vacuolation and destruction of nerve cells in the neighborhood of the injection, and there are also lymphocytic infiltrations and subependymal neuroglial proliferation Such, then, are the appearances within the first 4 days With the further progress of the infection considerable hemorrhage occurs in the parenchyma, and there is destruction of nerve cells The polymorphs become largely necrotic, and pyknotic debris is found in the meninges. The cellular infiltrations in the meninges, and around the vessels, are now composed mainly of lymphocytes, mononuclears, plasma cells, erythrocytes, and fibroblasts, with some few remaining polymorphs In animals surviving for some time the main lesions are meningeal and perivascular infiltrations with small lymphocytes The optic thalamus, midbrain, and pons show a particular tendency to be attacked (Da Fano, 1923).

Inclusion bodies A number of different types of inclusion body has been investigated experimentally by Da Fano, Cowdry, and Nicholson, and others

1. Nuclear inclusions are either small basophilic granules (Da Fano, 1923), or larger oxyphilic bodies—*neurocorpuscules encephalitiques* (Levaditi and Harvier, 1920 *a*, Levaditi, Harvier, and Nicolau, 1922) Both of these are probably degenerative products of chromatin produced by virus action.

2 Large extra- and intra-cellular bodies are rounded and acidophilic, varying from 0 6 μ to 5 μ in diameter, found mainly in endothelial and mononuclear cells,

Certain chemicals introduced into the skin prior to an intracutaneous inoculation were found to enhance or retard the development of the infection (Olitsky and Schlesinger, 1941).

After intravenous inoculation, a primary myelitis may develop (Doerr and Hallauer, 1936).

Young animals have been shown to be more susceptible to the extraneural inoculation of virus than older ones (Lennette and Koprowski, 1944); in agreement with this principle it has been found that suckling mice are readily infected by the nasal route (Berry and Slavin, 1943). Virus was found to pass to the brain by the trigeminal and olfactory pathways (Slavin and Berry, 1943 *a*), and it could also be found in the lungs due to direct aspiration, virus was also found to disseminate by the blood to reach the liver, spleen, and less commonly the adrenals and marrow, inclusions could be found in the lymph nodes draining infected organs (Slavin and Berry, 1943 *b*).

Young (2-week) mice can also be infected by intracutaneous inoculation and scarification of the pad, and experiments on the method of spread have been carried out by Evans, Slavin, and Berry (1946) They proved that if the inoculated foot was amputated after 2 hours, the CNS was not invaded by virus passing along nerves, *some animals died of encephalitis, however, virus reaching the brain from* metastatic foci in the viscera, these organs became infected by blood or lymph spread Amputation after 24 hours had no effect, animals dying with the paraplegia characteristic of infection reaching the CNS by nerve paths direct from the foot.

Infected mice were more susceptible to the effect of glucose injected intraperitoneally than normal animals (Hoyt, Holden, and Rawson, 1939).

The administration of insulin or metrazol before the intraperitoneal or intracerebral injection of virus had no influence on the result, metrazol given after an intraperitoneal injection did not facilitate the passage of virus to the CNS (Holden, 1940).

D. Rats

Rats can be infected by corneal inoculation (Teissier, Gastinel, and Reilly, ... ss, 1925 *b*; Smith, Lennette, and Reames, ... on may give rise to a primary myelitis ... in vitamins B_1 and B_2 are not definitely ... than healthy rats (Cowdry, Lucas, and Neff, 1935).

E. Monkeys

M rhesus cannot be infected with herpes, but callithrix monkeys can be infected by intradermal inoculation (Teissier, Gastinel, and Reilly, 1925) Crusted papules or vesicles appear but the infection remains strictly dermotropic without generalization Callithrix monkeys can be infected after several intracranial injections (Lépine, 1929, Levaditi and Lépine, 1929) Cebus monkeys, after intracerebral injection, may develop a chronic type of encephalitis resembling the human disease, both clinically and histologically (Zinsser, 1929, McKinley and Douglas, 1930) Lesions resembling human encephalitis have also been produced in chimpanzees (Delorme, 1929) *M synicus* and *M cynomolgus* can also be infected (Blanc and Caminopetros, 1921 *a*)

F. Cats

These animals are susceptible to intracerebral injection (Remlinger and Bailly, 1925, 1926 *c*, Urbain and Schaefer, 1929) Doerr and Schnabel (1921 *b*) were unable, however, to infect by this route.

2. *Intracranial injection* gives rise to an encephalitis (Blanc and Caminopetros, 1921 *c*). The virus was said to lose its pathogenicity for the rabbit after intracranial passage (Dimitrieff, 1926, Rose and Walthard, 1925–6). Flexner (1928 *b*), attempting to repeat this work, came to the conclusion that these results had only been achieved because a strain of low virulence had been used. Olitsky and Long (1928) carried out experiments with the weak encephalitic strain "C," and found that when injected intracerebrally no infection developed By means of a special double injection intracerebrally and corneally, however, the infection was transmitted

3. *Intravenous injection* may produce primary myelitis (Doerr and Hallauer, 1936).

4. *Dermal injection.* After tarring the skin a zoster-like lesion may develop (Teague and Goodpasture, 1923–4), but lesions can be produced by simple scarification (Bedson and Bland, 1928).

5. *Pad injection* Various workers have shown the pad of the foot to be susceptible (e g, Gildemeister and Herzberg, 1925; Bedson, Maitland, and Burbury, 1927). When inoculated with human vesicle fluid the sole of the foot appears hot, red, and swollen in two days, and by the third day vesicles appear, and soon coalesce. Alternatively, after rubbing virus into the scarified skin, vesicles appear by the second day. Although recovery is the rule, generalization may occur (Bedson and Crawford, 1927, Teissier, Gastinel, and Reilly, 1929; Urbain and Schaefer, 1929). After 4 to 8 days paralysis of the affected paw develops, and paraplegia with complete paralysis may occur. After injection of the pad, Nicolau bodies (see above) may be found in the malpighian cells.

6. *Intragastric injection* After introduction of virus into the stomach, infection results (Urbain and Schaefer, 1929).

C. Mice

Mice can be infected intracranially (e.g, Blanc and Caminopetros, 1921 *c*, Andervont, 1929, *a*, *b*, Fischl and Schaefer, 1929, Schaefer, 1930, Gildemeister and Ahlfeld, 1936, 1937, Burnet and Lush, 1939 *c*).

Steigman and Scott (1942) have described a method for the rapid adaptation of human strains to the mouse brain Rabbits are inoculated on the cornea, and when the infection is established, the nictitating membrane is removed aseptically, ground, and a suspension inoculated intracerebrally in mice Signs of infection usually take up to 10 days to develop, but on passage the incubation is shortened to 3–4 days

Herpes strains can be titrated by intracerebral inoculation (Levaditi and Bonét-Maury, 1941) The titer can be expressed by calculation of the LD_{50} (Bonét-Maury, 1941). It is important to realize that some of the mice that fail to die in titration experiments may have contracted a subclinical attack, and should be challenged by a subsequent injection of virus before concluding that they are not infected (Levaditi, 1941 *b*)

Mice can also be infected more or less readily (according to the strain of virus) by pad, corneal, intra-ocular, intracutaneous, subcutaneous, intraperitoneal, and intravenous inoculations, and by nasal instillation (e g, Andervont, 1929 *b*, Gildemeister and Ahlfeld, 1936, 1937, Burnet and Lush, 1939 *c*, Findlay and MacCallum, 1940) Certain special observations will now be mentioned

Following inoculation into the vitreous, it was found that virus spread by the trigeminal nerve caused lesions in the gasserian ganglion and nucleus of the fifth nerve, with the development of encephalitis (King, 1940)

The HF strain was found to be very invasive on intraperitoneal inoculation, but less infective on intranasal instillation, while it failed to produce infection by the subcutaneous route (King, 1940) It is generally agreed that the subcutaneous route is one of the least effective.

usually granular, body often filling the whole nucleus, although smaller forms are described. The bodies have been repeatedly found in human and in all kinds of experimental animal lesions After local injections of virus into the retina, various mucosae, adrenals, liver, ovary, etc, Goodpasture and Teague (1923–4 *a*) came to the conclusion that the presence of these bodies was always associated with that of the virus The nature of these bodies has been investigated in different experiments

1. Cowdry (1930) studied the inclusions as found in the testicles of infected rabbits, and compared them with somewhat similar inclusions found in virus "III" infection The most important results of this work were that the bodies were found to be resistant to fixative, indicating a protein constitution, and they did not give a positive Feulgen reaction, suggesting that they were not composed of chromatin

2. The development of these structures has also been studied in tissue culture Rivers *et al.* (1929) grew cornea by the tube technique and noted the development of typical Lipschutz bodies in virus-infected specimens Andrewes (1930) found Lipschutz bodies to develop regularly in infected cultures, and claimed that immune serum would prevent their occurrence Both Lipschutz bodies and granules which may possibly be the "minute bodies" of Da Fano have been found in the chorio-allantois of infected fertile eggs (Dawson, 1933) Inclusions develop in human chorion and amnion grafted on the chorio-allantois Anderson (1940) found inclusions in many different types of cell in the infected embryo

3. Micromanipulation studies have been recorded (Baumgartner, 1935 *a* and *b*) which would appear to indicate quite definitely that these bodies contain the living virus, for herpetic keratitis has been reproduced by a single washed inclusion

4. Micro-incineration studies (Rector and Rector, 1933) have shown these structures, when in an early stage, to contain considerable quantities of inorganic material which becomes progressively less as the body ages The mature herpetic intranuclear body may contain no inorganic matter, thus differing markedly from intracytoplasmic bodies in which inorganic material is quite abundantly present.

5. The ultracentrifuge has been utilized by Lucas and Herrmann (1935), and it has been shown that the intranuclear body and the chromatin have different properties. The body is lighter than the chromatin and passes to the opposite pole of the nucleus, sometimes chromatin has to pass through the substance of the body, and if so is found to be separated from it by a distinct space These facts make it unlikely that the body is composed of chromatin

6. Vaccinia and herpes can both grow in individual rabbit corneal cells and produce their characteristic inclusions (Syverton and Berry, 1947).

In conclusion it may be said that opinion is tending more and more to uphold the original view of Lipschutz that the bodies described by him are structures consisting of the living virus, and not degenerative material derived from chromatin. It is possible that Nicolau's bodies represent the initial, and the Lipschutz body the later, stages of growth

Intracellular position of herpes virus. The organism would appear to occupy an intracellular position in infected tissue, such as brain If such tissue is homogenized, that is to say, so treated mechanically that every cell is ruptured and its normal structure destroyed, the resultant product is very much more active than the same material before homogenization (Buggs and Green, 1936). The virus is probably not, however, very firmly attached to the cells as it has been shown to be freely diffusible from infected brain Thus, if infected tissue be placed in glycerol along with normal brain, subsequent tests show that the virus leaves the infected brain to enter both the glycerol and the normal tissue (Remlinger and Bailly, 1926 *a*). The results of experiments by Perdrau and Todd (1936) also support the intracellular position if virus is injected in a testis and suspensions thereof are prepared, methylene blue does not destroy the virus in the presence of light after 18 hours, but virus is destroyed if the suspension is prepared earlier

G. Dogs

Dogs are susceptible only to intracerebral injections of virus which has been passed through cats (Remlinger and Bailly, 1926 *d*, Urbain and Schaefer, 1929).

H. Other Susceptible Animals

The following animals have been used. pigeons, geese, and hedgehogs (Remlinger and Bailly, 1927); porcupines (Remlinger and Bailly, 1931); and foxes (Levaditi, Lépine, and Schoen, 1929).

Cotton rats can be infected cerebrally and nasally (Florman and Trader, 1947). Hamsters are very susceptible to intracerebral and less so to intraperitoneal inoculation (Wenner, 1944; Zarafonetis *et al*, 1944).

I. Simultaneous Injection of Herpes and Rabies

If mice are injected intracerebrally with street virus and herpes, and the brain passed in series, rabies virus is quickly suppressed and only herpes is passed (Levaditi, 1942 *a*).

MORPHOLOGY OF HERPES VIRUS

Elementary bodies have been described by Taniguchi *et al.* (1934). These bodies can be stained by Giemsa's and other methods (see Ch. III), and by direct micrometry appear to be about 0 25 μ in diameter. They have been found in the vesicular fluid of early cases of herpes labialis, and have also been demonstrated [illegible] ing free. [illegible] nan her-

The size of the virus particles has been estimated by means of Elford's gradocol membranes, Elford (1933) and Elford *et al.* (1933) giving the size as from 0.1 μ to 0.15 μ, while 0.1 μ to 0 3 μ are the limits defined by Levaditi *et al.* (1936) The figure varies according to the source of the virus and the animals used to test the filtrates (Levaditi, 1941 *a*) By centrifugation the size has been calculated to fall *between 0.18 μ and 0 22 μ (Bechhold and Schlesinger, 1933).*

Inclusion bodies have already been described and only 3 varieties are worthy of further discussion. First, the "minute bodies" described by Da Fano (1923) and other workers, secondly, Nicolau bodies, and thirdly, the larger bodies of Lipschutz (1921 *a, b, c*).

(*a*) The "minute bodies" occur in the cytoplasm of infected cells in experimental encephalitis of the rabbit and usually stain as basophilic granules. The investigations of Cowdry and Nicholson (1923) have shown that these bodies are unlikely to be of nuclear or mitochondrial origin. Judgment must, however, be reserved as *they have not been found commonly.*

(*b*) Nicolau aroused considerable interest by reporting the presence of small granular inclusions in infected tissues of the rabbit and guinea-pig (Nicolau, 1937, Nicolau and Kopciowska, 1937, 1938) These bodies stain, usually blue, by Nicolau's oxalated methyl-blue-acid-fuchsin method, they measure from 0 1 μ to 0.5 μ in diameter and resemble typical elementary bodies as they appear when inside cells The bodies occur in the cytoplasm and nucleus, both of neuronal and neuroglial cells in the rabbit's brain They also occur in the malpighian cells after pad injection in the guinea-pig After neural injection of rabbits they can be found in and between the nerve fibers

With the progress of the infection the granules may fuse to give larger eosinophilic structures in the cytoplasm or nucleus These nuclear inclusions resemble Lipschutz bodies, while the smaller cytoplasmic granules resemble Da Fano bodies

(*c*) *The Lipschutz body.* This has undoubtedly the strongest claim to be regarded as the typical inclusion body of herpes febrilis It consists of an eosinophilic,

The histological changes occurring in the infected embryo have been particularly studied by Anderson (1940). After inoculation of the chorio-allantois, small plaques were found in 48–72 hours, with inclusions in ectoderm and mesoderm These cells proliferated, and there was a mild inflammatory reaction. Ectodermal cells underwent necrosis and desquamation On serial passage, the severity of the lesions increased and they became more destructive than proliferative; petechial hemorrhages and thromboses in small vessels were found. The membranes of older embryos were more resistant than those of younger.

On amniotic inoculation, Anderson found inclusions in the amniotic ectoderm, mesoderm, and muscle cells, in the embryonic skin and pharyngeal epithelium. When virus was inoculated by scarification of the skin, there were necrotic changes in the epithelium, and nuclear inclusions were found also in striated muscle. On

multiplication. The epithelial cells proliferate, and undergo necrosis This mode of spread was found on chorio-allantoic and amniotic inoculation

(2) Virus invaded the blood stream at the site of inoculation, and was disseminated, causing a generalized infection Inclusions were found in the endothelium of larger vessels and capillaries. On successive membranal passage, the virus produced more severe lesions in the endothelium, and mesoderm such as cardiac muscle and liver; inclusions occurred in these sites and also in interstitial tissue in the lungs, spleen, and subserosa of the gut, glomerulonephritis might be seen. These metastatic lesions could be prevented by the intravenous administration of antiserum

(3) Virus might spread by nerve pathways Following subcutaneous injection, an ascending myelitis might result, and after intracerebral inoculation a descending encephalomyelitis.

Reaction to Physical Agents

Heat. 56° C for ½ hour, or 37° C for 24 hours, destroys the virus (Löwenstein, 1919, 1920) The thermal inactivation time of two stock strains was 80 hours at 41 5° C., a recently isolated strain was destroyed in 50 hours at this temperature. The neurotropic factor of these strains was more resistant to heat than the dermotropic (Boak, Carpenter, and Warren, 1940). Radiothermy (107° C for 1½ hours) failed to cure herpetic encephalitis of rabbits (Kopeloff and Holden, 1931–2)

Ultrapressure The virus is destroyed by a pressure of 3,000 atmospheres (Basset *et al*, 1935)

Centrifugation. Bedson (1927) showed that the virus could be deposited at 5,000 r p m in 2 to 2½ hours

Electrical reactions and effect of pH The iso-electric point is between 7.2 and 7 6 (Bedson and Bland, 1929 *a*) and the virus particles are negatively charged at pH 7 8 to 6 8 (Nicolau and Kopciowska, 1930 *a*) Infected rabbit brain, at laboratory temperature, keeps its activity in liquids of pH 4 6 to 8.4 (Nicolau and Kopciowska, 1930 *c*)

Ultraviolet irradiation Virus, in a fluorescent medium, is very sensitive (Levaditi, 1942 *b*) Atomized virus is sensitive to UVL of wave length 2537 Å (Edward, Lush, and Bourdillon, 1943)

Reaction to Chemical and Biological Agents

Glycerol Strains vary somewhat in their resistance to 50 per cent glycerol, while some become modified in virulence, others retain their activity almost unimpaired for a year or more Levaditi and Harvier (1920 *b*) showed that the brain

OTHER PROPERTIES OF HERPES VIRUS

Filtrability

The virus passes the following filters· Nordmayer-Berkefeld (Luger and Lauda, 1921 *d*), Chamberland L_1 (Levaditi and Harvier, 1920 *a*, Blanc, 1921), and L_2 (Perdrau, 1925), Mandler (Greenbaum and Harkins, 1925) Ward and Tang (1929) have shown it to be more readily filtrable when suspended in broth than in saline, and using this technique, found Berkefeld V filtrates to be infective. The virus was shown to pass through collodion sacs by Levaditi and Nicolau (1923 *b*), and through collodion membranes by Zinsser and Tang (1927) before the introduction of Elford's gradocol filters.

Tissue Cultivation

The virus grows readily in media of the Maitland type (Gildemeister *et al*, 1929, Andrewes, 1930; Haagen, 1931, 1933; Saddington, 1932). The maximum growth occurs at 34°–35° C. (Thompson and Coates, 1942). Virus can be propagated on agar slopes with finely minced chick embryo tissue on the surface (Cheever, 1939, Cheever and Willmert, 1942).

Growth in the Fertile Egg

Herpes virus grows on the chorio-allantois and produces pocks, typical intranuclear inclusions being found histologically (Saddington, 1932, Dawson, 1933, Burnet, 1936, Burnet and Lush, 1939 *a;* Burnet, Lush, and Jackson, 1939 *a*, *b;* Anderson, 1940, Smith, Lennette, and Reames, 1941).

The HF strain is said to produce larger foci than most freshly isolated strains, the foci are proliferative-necrotic, and, microscopically, inflammatory cells can be found in the mesoderm (Beveridge and Burnet, 1946)

Burnet and his colleagues have used pock counting as a method of titrating virus or virus-antiserum mixtures (see also Schaffer and Enders, 1939, Gallardo, 1943, Florman and Trader, 1947, Rose and Molloy, 1947).

Schaffer and Enders (1939) have reported investigations on the effect of antiserum on chorio-allantoic infection. They found that serum inoculated on the membrane five minutes before, or at the same time as virus, prevented infection When serum was added five minutes later, 4–8 per cent of the virus was *already* "fixed" by the tissues, and by 18 hours all the particles were insusceptible to the neutralizing action of the serum.

After adaptation to chorio-allantoic passage, virus generalizes and brings about *death of the embryo in 3–5 days* *Anderson (1939, 1940) in one series* of passages, found that when the neurotropic HF strain had been passed serially 70 times, its virulence for the embryo was greatly increased, while keratitis-producing power *for the rabbit was lost* *Beveridge and Burnet (1946)* working with a mouse passage strain of HF, found that virulence for mice was lost, although it still produced keratitis in the rabbit

After yolk sac inoculation in 8-day eggs, the virus generalizes and can be recovered in high titer from the amniotic and allantoic fluids (Nagler, 1946, Rose and Molloy, 1947) After 3 days incubation at 35° C, the amniotic fluid contained at least 10^7 living particles per c c The protein content of the fluid in living infected 11-day embryos was 0·012 per cent compared with the normal figure of 0·005 per cent

The effect of amniotic inoculation has been investigated by Burnet (1940), and Anderson (1940) *The latter also infected embryos subcutaneously, by scarification,* and intracerebrally Beveridge and Burnet (1946) found that embryos inoculated when 8 days old died in 48 hours, and the amniotic fluid titered 10^{-7}–10^{-8} per c.c , 6-day embryos also died and gave fluid of high titer

the virus neutralization technique or by complement fixation (see, e g, Zinsser and Tang, 1929, Hudson, Cook, and Adair, 1936; Gildemeister and Ahlfeld, 1937, Burnet and Williams, 1939, Armstrong, 1943, Humphrey and McClelland, 1944)

Virus neutralizing antibody can be detected by inoculation of the chorio-allantois with serum-virus mixtures (Burnet and Lush, 1939 *b*, Burnet and Williams, 1939, Gallardo, 1943; Nagler, 1946, Rose and Molloy, 1947). Alternatively, the mixtures can be inoculated intracerebrally in mice (Smith, Lennette, and Reames, 1941, Scott, Steigman, and Convey, 1941, Evans, Bolin, and Steves, 1945, Slavin and Gavett, 1946 *a*). Rabbits or other susceptible animals can also be inoculated intracerebrally or by other routes.

Antibodies are less commonly found in the sera of children than of adults, antibody develops in the sera of children during convalescence from primary herpetic stomatitis (Weyer, 1932–3; Burnet *et al*, 1939; Burnet and Williams, 1939, Gallardo, 1943, Buddingh, 1946, Nagler, 1946, Rose and Molloy, 1947). Antibody is very much more frequent in children from crowded areas Once developed, herpetic antibody probably remains throughout life, so that approximately 75 per cent. of sera from any unselected group of adults show virus neutralizing properties (Andrewes and Carmichael, 1930)

Tests on selected subjects show that the serum of herpetic persons regularly contains antibody, while it is absent from the serum of normal people. Brain (1932) demonstrated this by the complement fixation test, and it can be shown also by virus neutralization tests (e g, Andrewes and Carmichael, 1930, Burnet and Lush, 1939 *a*, Burnet and Williams, 1939, Nagler, 1946).

It has been said that antibody is usually absent in the sera of patients suffering from encephalitis lethargica (Gay and Holden, 1931).

When antibody is present in the sera of children or adults it is so to high titer, sera are rarely found where antibody is present to a low or moderate titer only; this is because herpes is a chronic infection and presumably there are constant stimuli to antibody production (Burnet and Lush, 1939 *b*, Burnet, 1945).

Thomas (1941) has reported the apparent cure of a case of recurrent herpes by intracutaneous desensitization with autogenous blood serum withdrawn at the height of an attack.

Skin test. Nagler (1944, 1946) has shown that herpetic subjects give a positive skin reaction to a heated antigen prepared from amniotic fluid This positive reac-

Herpetic Immunity in Animals

In marked contrast to the state of affairs in man a general immunity can be readily developed in certain animals This immunity arises either on recovery from infection or after protective vaccination. The exact rôle which serum antibodies and tissues play in the development of this immunity is uncertain There is no evidence that leukocytes are concerned (Silber and Shubladze, 1946).

A. Natural immunity.

Rabbits are generally regarded as being universally susceptible to herpetic infection, but a case has been recorded in which injection by numerous routes was withstood, there having been no previous contact with the virus in any way, while the serum of the animal exhibited no virus neutralizing properties (Teissier, Gastinel, and Reilly, 1928) The newborn of actively immunized mice are immune to skin infection for 2 weeks after birth (Andervont, 1929 *b*) They also resist nasal instillation, resistance is probably due to the imbibition of antibody in the milk (Berry and Slavin, 1943).

of a rabbit suff [illegible] preservation in glycero [illegible] bstance in fresh brain wh [illegible] troyed by glycerol, thus "unmasking" the virus. Da Fano and Perdrau (1927) found that the brains of rabbits suffering from chronic herpetic encephalitis might prove to be inactive when fresh, but active after glycerolization, Perdrau (1938) found that *alumina* would also activate virus. Similar results have been recorded by Nicolau and Kopciowska (1930 *b*).

Electrolytes. Virulence is rapidly lost in salt solutions at 37° C., complete inactivation often taking place in 4 to 5 hours. Serum (Zinsser and Tang, 1926) and distilled water (Gay and Holden, 1929) do not, however, have this property.

Oxygen. Rapid deterioration of virus occurs in the presence of oxygen, but under anaerobic conditions viability is prolonged (Zinsser and Tang, 1929), especially if cysteine is present (Zinsser and Seastone, 1930). Suspensions in broth can be inactivated by oxidation and reactivated on subsequent reduction (Perdrau, 1932).

Other agents. The virus is adsorbed and neutralized by carmine powder, adsorbed but not neutralized by charcoal, and is precipitated with the carbon dioxide globulins (Gay and Holden, 1929). Bile destroys the virus, but it is resistant to neutral red (Blanc, Tsiminakis, and Caminopetros, 1921). Herpes virus is sensitive to the virus inactivating agent of nasal secretion, saponin, sodium desoxycholate, and sodium lauryl sulphate (Burnet, Lush, and Jackson, 1939 *b*; Burnet and Lush, 1940) It is inactivated rapidly by potassium salicylate (Cooke and Best, 1941), and ascorbic acid (Holden and Resnick, 1936, Holden and Molloy, 1937).

Chemotherapy Prontosil and similar compounds had no prophylactic or curative effects in rabbits injected intracranially with virus (McKinley *et al.*, 1939). Vitamin C, pitressin, and sulfanilamide were ineffective in the treatment of encephalitis (Flexner, Chassin, and Wright, 1940). Cutting *et al* (1947) found antibiotics and a number of chemotherapeutic drugs to be ineffective in eggs and mice.

Affinity for Epithelial Tumors

Herpes survives locally when inoculated into an epithelioma of the mouse, thus resembling neurovaccine (Levaditi and Nicolau, 1922 *b*). In contrast to neurovaccine, *however, herpes is not found locally in Shope's papillomatous tumor* whether injected into the tumor or intravenously (Levaditi and Schoen, 1936)

IMMUNITY

Herpetic Immunity in Man

As recurrent attacks are so common one would not expect any significant immunity to be conferred by herpetic infection It has, however, been shown that recurrent vesicles are not found in precisely the same spot on each occasion (Dubreuilh, 1900) This probably does not indicate local immunity, as two separate injections of virus have been given at a month's interval into the same site, with positive results on each occasion (Teissier, Gastinel, and Reilly, 1926 *a*).

Prevention and treatment Brain (1937) has suggested that when the antibody content of the serum of persons subject to herpes falls below a certain level active herpetic lesions occur To prevent such attacks, therefore, the antibody content should be raised by vaccination, either with the patient's own vesicular fluid (Hruszek, 1933), or with a 10 per cent formolized suspension of infected guinea-pig pads (Brain, 1936), or other tissue containing active virus (Teissier, Gastinel, and Reilly, 1926 *a*). It seems that some benefit may follow such treatment in cases of recurrent herpes. Repeated vaccination with calf lymph is said to cure recurrent herpes (see Foster and Abshier, 1937, Woodburne, 1941).

Serum antibodies Antibodies can be detected in the sera of convalescents by

1929 *b*). Kanazawa (1938) has succeeded in immunizing them with phenolized virus injected intraperitoneally, intracerebrally, or cutaneously. Burnet and Lush (1939 *c*) immunized mice by intranasal instillation of living, and intraperitoneal inoculation of formol-killed, virus.

C. Active immunity to superinfection (Magrassi's phenomenon).

A considerable amount of work has been carried out on the reaction of the rabbit to 2 separate injections of herpes virus at definite intervals (Magrassi, 1935, 1935–6 *a*, *b*, Doerr and Seidenberg, 1936–7; Hallauer, 1937, Doerr and Kon, 1937) Thus, when a second (intracerebral) injection is given a few days after a preliminary (corneal or intradermal) injection, mutual extinction occurs and no characteristic encephalitis develops The original papers are extremely detailed but the following are their main findings

1. *Corneal inoculation.* After a corneal inoculation with a nonencephalitogenic [illegible]

its normal pathogenic action is withstood, the animal remaining well This rapidly developing immunity is "solid" and permanent (Magrassi)

If instead of a nonencephalitogenic an encephalitogenic strain be used for the preliminary corneal inoculation, then the second intracerebral injection not only fails to produce encephalitis itself, but prevents its development as the natural sequel of the primary keratitis Doerr and Seidenberg showed that this immunity to cerebral reinjection arises earlier when an encephalitogenic strain is used for the primary corneal inoculation than one which is nonencephalitogenic. They showed that this is due to the fact that of the two strains the more virulent spreads to the brain more rapidly Spread occurs along nerves, and virus can be demonstrated in such nerves for 2 to 4 days, "autosterilization" occurs thereafter and the nerve (like the brain later on) appears devoid of virus

Examination (by animal injection) of brains soon after the second (intracranial) injection shows that the virus is actually demonstrable for some days Immunity to superinfection only arises when virus is actually present in the brain at the time of the second injection Eventually "auto-sterilization" occurs and the brain appears to be virus-free. Actually, however, the reaction is more a partial neutralization than a complete destruction of virus, because the brain is still capable of inciting the production of active immunity on injection into other animals.

It is not possible to prevent the development of consecutive encephalitis after corneal inoculation if the second inoculation is given on the other cornea Mutual extinction does not occur in this case even though virus from each injection must meet in the brain

2 *Intradermal injection* Following a single intradermal injection of virus, either encephalitic or myelitic symptoms develop on the eighth to tenth day. It is possible to prevent the occurrence of these by a second injection of active or formolized virus, but only if given intracerebrally and on the seventh to eighth day This is another example of the 2 infections cancelling each other, and again the mechanism appears to depend on virus neutralization rather than destruction

3 *Possible explanations* The undoubted neutralization which occurs does not appear to be due to any demonstrable virus neutralizing power of the immune brain There is, indeed, some increase of serum antibodies in these animals, but such increase does not seem sufficient to account for the whole phenomenon, because, although formolized virus injected intradermally gives a higher anti-body titer than active virus, animals immunized therewith possess a lower grade cerebral immunity than do those receiving living virus It should be noted that the inocu-

B. Active immunity following infection and vaccination.

On recovery from herpetic infection rabbits are usually immune to reinoculation. Thus, after an attack of keratitis in the rabbit the same eye is immune to further herpetic infection (Lowenstein, 1919, 1920, Blanc and Caminopetros, 1921 *a*). It seems probable that if the initial keratitis is sufficiently severe the other eye also will become immune (Doerr and Vochting, 1920); and even subdural injections may be without effect (Blanc and Caminopetros, 1921 *b*, Doerr and Schnabel, *1921 a*).

In certain cases, if a second corneal inoculation is performed on an eye recovered from keratitis, an intense keratoconjunctivitis develops in a few hours, this being an example of hypersensitivity (Fontana, 1921).

Numerous authors have succeeded in immunizing rabbits against reinfection (Perdrau, 1925, 1938, Zinsser and Tang, 1926, Fournier and Levaditi, 1928, Teissier *et al.*, 1928, Urbain and Schaefer, 1929, Vieuchange, 1936, Hallauer, 1937, Magrassi and others as described below)

The inoculum usually consists of living virus, either fresh or glycerolated, formolized virus may be of use (Urbain and Schaefer, 1929). To produce immunity repeated large doses are usually given, but Perdrau (1925) reported that immunity developed in *11 days after one intradermal injection and lasted over* 3 months

As *regards the routes of injection, a great variety is available: intradermal,* dermal, intranasal, intravenous, corneal, instillation of the external auditory meatus, intramuscular, intraneural, and subcutaneous injections may all be used.

If the resultant immunity is marked, even intracranial injection is resisted, but if it is less well developed, intradermal injection only may be tolerated

Perdrau (1925) found that immunity (tested by intracranial injection) was most readily acquired when virus was injected intradermally. As regards the actual source of the virus used for immunization by this route, human vesicle fluid proved inactive, but infected rabbit brain was active. After one passage through rabbit brain, however, the human vesicle fluid was able to induce immunity. If a second intradermal injection was given within 11 days of the immunizing dose, encephalitis developed

Following intracranial injection of immune rabbits the virus cannot be recovered from the brain after 2 hours During the first few hours following such an injection an increasing polymorph infiltration is found, but this soon disappears as the virus is overcome (Nicolau and Kopciowska, 1929).

It has been suggested that the mechanism of immunity following vaccination depends on a mild subclinical infection, as rabbits frequently die of encephalitis during the course of injections (Perdrau, 1925, Fournier and Levaditi, 1928) Animals may even die of encephalitis 6 months after injection with living virus, although earlier they have been proved resistant to an intracerebral injection, active free herpetic virus can be isolated from the brains (Perdrau, 1938) Hallauer (1937) showed that immunity of the spinal cord advanced *pari passu* with the spread of active virus therein Animals injected with neutral mixtures of virus plus immune serum are not rendered resistant (Zinsser and Tang, 1926).

Guinea-pigs can be readily protected against subsequent infection by inoculation of virus on the plantar skin This immune state develops after about 5 days and lasts *for at least 130 days (Bedson and Crawford, 1927).* These animals can also be immunized by the intraperitoneal route (Olitsky and Long, 1928), or by scarification on the hairy skin followed by intramuscular injection (Bedson and Bland, 1928). Bedson (1931) found that formol-killed virus was effective.

Monkeys, too, can be rendered immune after repeated intradermal injections, the immunity lasting at least 4 months (Teissier, Gastinel, and Reilly, 1925)

Mice have been immunized by repeated intraperitoneal injection (Andervont,

injected prophylactically prior to corneal inoculation (Kitchevatz, 1934) It may also prevent herpetic infection in mice (Andervont, 1929 *b*, Gildemeister and Ahlfeld, 1937, Burnet and Lush, 1939 *c*, Berry and Slavin, 1943). Guinea-pigs may be hyperimmunized, and their serum can confer passive immunity (Bedson and Crawford, 1927). Sera can be produced in chickens (Anderson, 1940).

Evans, Slavin, and Berry (1946) have studied passive immunity in 2-week-old mice infected in the foot pad. When serum was given intraperitoneally at the same time as the virus was inoculated, most mice were protected, the virus being presumably destroyed locally. Serum given at 12 hours after virus inoculation had some but less effect, while up to 48 hours, the infection was retarded. The partly protective effect of serum given after about 24 hours was probably due to a direct action on virus in the CNS, this was confirmed in experiments where serum was given to mice in whom the primary site of inoculation was amputated, and where a local action was thus excluded. They suggest that serum can protect young mice by neutralizing virus before it enters epithelial cells, by preventing virus in epithelium from invading nerves or by a direct antiviral effect in the cells of the CNS.

F. Properties of tissues of immune animals.

It has been claimed that the brains of actively immunized rabbits can neutralize virus *in vitro* (Levaditi and Nicolau, 1922 *a*, Zinsser and Tang, 1926, Teissier *et al*, 1928, Urbain and Schaefer, 1929), and that the adrenal of such animals has the same property (Teissier *et al.*, 1928)

usual incubation period was markedly shortened This effect he attributed to an "aggressin" It appears that this "aggressin" does not exert its full action in the fresh state, but only after glycerolization.

RELATIONSHIP OF HERPES FEBRILIS TO OTHER VIRUSES

1. Zoster

On clinical grounds there appears to be little similarity between herpes febrilis and zoster, although both are characterized by vesicle formation Thus, the course of zoster is more prolonged than that of febrile herpes, zoster most frequently occurs on the trunk, while herpes does so rarely, the bullae of zoster are considerably larger than the small vesicles of herpes, zoster occurs unilaterally, along the distribution of a nerve, and pain is a marked feature, while herpes usually occurs at the mucocutaneous junctions and may be relatively painless, zoster seldom recurs, but herpes febrilis does so frequently.

Herpes virus gives rise to characteristic lesions in animals which cannot be produced with zoster virus It should be remembered, however, that both diseases are thought to spread via the nerves, and changes in the gasserian ganglion have been recorded in cases of herpes febrilis (Howard, 1905), as well as in zoster In addition, Teague and Goodpasture's (1923–4) work showed that the eruption produced by herpes febrilis could be made to assume a zoster-like distribution (*vide supra*)

Immunological observations do
lationship exists between the two vi
zoster fluid induces no immunity to
and Lauda, 1921 *b*), and no comp
and herpetic sera (Netter and Urbain, 1924)

There seems to have been little support for the suggestion of Teague and Goodpasture that cases of an intermediate nature occur which cannot definitely be allotted to either group, and that zoster is produced by a virus differing from that

lations can be brought to mutual extinction only if the second is given intracerebrally, no other route being effective.

The precise explanation of this phenomenon of immunity to superinfection may depend on a cerebral tissue reaction of a type hitherto unrecognized It appears to fall into the category of the "interference phenomenon," a number of other examples of which are described in this book.

D. Serum antibodies.

There is definite evidence that herpes virus can unite with antibody *in vitro* (Bedson, 1928, Smith, 1930). Thus, the latter showed that herpes-infected tissue absorbs the *homologous antibody from a specific serum, and from a mixture of* antiserum to herpes and vaccinia, leaving the antibody to vaccinia. Burnet and Lush (1939 *a*) have carried out studies on the union between virus and herpetic antibody—making use of the egg membrane as an indicator of the presence of virus They found that virus is inactivated by antiserum, and if enough time is allowed, an equilibrium is reached where concentration of antiserum × percentage of survivors is constant. The union was found to be reversible by dilution for some time after the equilibrium was attained, but with strong mixtures partial irreversibility subsequently developed.

Complement fixation occurs between herpes hyperimmune serum (guinea-pig) and virus antigen, when at least 4 MHD of complement may be deviated (Bedson and Bland, 1929 *b*). The fixation time should be prolonged, overnight in the refrigerator being recommended Stroian (1929) found that serum and extracts of testicle, ovary, adrenals, and other organs of actively immune rabbits fixed complement in the presence of herpetic antigens. Complement fixation has also been demonstrated with the serum of an actively immunized monkey, the antigen being prepared from herpetic crusts (Todorovitch, 1925).

Viruciding have been demonstrated in the serum of actively immunized rabbits by a number of workers (Flexner and Amoss, 1925 *c;* Zinsser and Tang, 1926; Bedson and Crawford, 1927, Schultz and Hoyt, 1928, Gay and Holden, 1929. Smith, 1931 *a*). Similar antibodies have been demonstrated in *actively immunized* guinea-pigs (Bedson and Crawford, 1927, Bedson and Bland, 1928), and mice (Gildemeister and Ahlfeld, 1937). Burnet and Lush (1939 *c*) titrated neutralizing antibody by the chorio-allantoic technique. Similar results are obtained by titrating antisera on the chorio-allantois or by inoculating mixtures of serum and virus intracerebrally in mice (Schaffer and Enders, 1939).

Opsonic experiments have also been carried out (Jamuni and Holden, 1934) These workers found that normal leukocytes aided in the inactivation of virus in the presence of immune serum (rabbit) Analogous results were obtained, however, *with immune cells and normal serum Either immune or normal cells* possessed a greater virucidal effect than immune serum alone, and this they attributed to opsonization of the virus particles

There is at present some difference of opinion concerning the rôle of antibodies in the mechanism of herpetic immunity Certain work, mentioned above, supports the view that immunity is dependent on the presence of herpes virus in the immune tissues (infection immunity) Other work has, however, tended more to support the rôle of antibodies Burnet and Lush (1939 *c*) for example, working with mice, concluded that the production of antibodies was the main factor in conferring acquired immunity—because immune bodies were produced by immunization with dead virus, and *passive immunity could be conferred* by high-titer herpetic antiserum

E. Hyperimmunization and passive immunity.

Rabbits may be hyperimmunized by repeated injections of virus (Zinsser and Tang, 1926) Such serum may have a favorable effect in preventing keratitis, if

strains have been obtained (e g., by Flexner and Amoss, 1925 *b*) which are as encephalitogenic as any isolated from encephalitis Florman and Trader (1947) found that two strains isolated from nervous disease in man were not more neurotropic in test animals than a mouth strain. The mouth strain was as dermotropic in the guinea-pig as was a nervous strain They concluded that the neurotropic and dermotropic properties of the virus depend on the host and not on the intrinsic nature of the strain. Further, although after corneal inoculation with herpes strains no symptoms of encephalitis may appear, the virus can none the less be found in the brain (Magrassi and others, *vide supra*)

Strains of virus have been isolated from encephalitis only on relatively few
...on with herpes possible,
...uids of the body. Gen-
...with proving the iden-
tity of the viruses isolated from encephalitis with those of known herpetic origin. This identity is now almost universally admitted as they cannot be distinguished by any known test.

Herpes virus can cause meningitis and encephalitis in man, but this syndrome does not resemble encephalitis lethargica in any essential respect.

of herpes only in virulence It is *probably safe to conclude, therefore,* that although affection of nerves occurs in both diseases, the viruses of herpes febrilis and zoster are distinct.

2. Varicella

Antigens made from herpetic vesicles do not fix complement with the convalescent sera of chickenpox cases (Todorovitch, 1925), vice versa, antigens made from chickenpox crusts give negative reactions with herpetic sera (Netter and Urbain, 1924).

3. Variola-vaccinia

Jenner (see Roxburgh, 1927) noticed that vaccination with calf lymph might fail to "take" in a subject suffering from herpes. This observation receives some support in that herpes is rarely found in cases of smallpox (see Roxburgh). The cornea of a rabbit immune to herpes has been shown to possess a partial immunity to variola; further, the serum of such an immune animal has a virus neutralizing action on variola (Gildemeister and Herzberg, 1925). These observations do not, however, afford adequate *grounds for postulating a relationship* between herpes and variola-vaccinia (for further work, see p 331). Vaccinia and herpes can be passed together cerebrally in rabbits, glycerol treatment of the brain destroys vaccinia long before herpes, so that the two agents can be separated by this means (Levaditi, 1941 *c*).

4. Virus "B"

This question is discussed at length in Chapter CI, here it may be mentioned that Sabin recorded a fatal case of ascending myelitis following a monkey bite (see Sabin, 1934). A virus ("B") was isolated, which although resembling, did not appear to be identical with, that of herpes Haber (1935) thought, however, that virus "B" was probably a genuine herpes febrilis strain.

5. Other Viruses

Herpes is not related to the viruses of infectious feline agranulocytosis (Lawrence *et al.*, 1943), or epidemic keratoconjunctivitis (Sanders and Alexander, 1943).

THE "HERPETICO-ENCEPHALITIC" GROUP OF VIRUSES

The herpes virus is one with both dermotropic and neurotropic properties The dermotropic properties are indicated by the ease with which the cornea and skin may be infected, while its neurotropism is shown by the encephalitis resulting from intracranial or other injections The variability of the characters of herpetic strains has been repeatedly stressed (Levaditi and Nicolau, 1922 *c*, Levaditi, 1922, 1926, Teague and Goodpasture, 1923–4, Flexner and Amoss, 1925 *a*, *b*, *c*, Lépine and Schoen, 1931). While some have only dermotropic, others have both dermotropic and neurotropic tendencies The French authors, in particular, hold that the two affinities are quite dissociable.

This problem is intimately associated with that of the possible relationship between the virus of herpes febrilis and strains isolated from epidemic encephalitis (this is fully discussed in Ch XCII) Here it may be mentioned that Levaditi and his collaborators have concluded that the two viruses form a group designated by them "herpetico-encephalitic" (e g, Levaditi and Nicolau, 1924, Levaditi, Nicolau, and Poincloux, 1924, Danila and Stroe, 1923 *a*, *b*, *c*, *d*, Levaditi, 1926) They suggest that at one extreme are found neurotropic strains which, granted a suitable host, may cause encephalitis, while at the other end of the scale are dermotropic strains possessed of no neurotropic properties Intermediate strains are, of course, encountered

It is questionable, however, whether this distinction really holds good, for

strains have been obtained (e.g, by Flexner and Amoss, 1925 *b*) which are as encephalitogenic as any isolated from encephalitis Florman and Trader (1947) found that two strains isolated from nervous disease in man were not more neurotropic in test animals than a mouth strain. The mouth strain was as dermotropic in the guinea-pig as was a nervous strain. They concluded that the neurotropic and dermotropic properties of the virus depend on the host and not on the intrinsic nature of the strain Further, although after corneal inoculation with herpes strains no symptoms of encephalitis may appear, the virus can none the less be found in the brain (Magrassi and others, *vide supra*).

Strains of virus have been isolated from encephalitis only on relatively few [illegible] contamination with herpes possible, [illegible] be in the fluids of the body. Gen- [illegible] cerned itself with proving the identity of the viruses isolated from encephalitis with those of known herpetic origin. This identity is now almost universally admitted as they cannot be distinguished by any known test.

Herpes virus can cause meningitis and encephalitis in man, but this syndrome does not resemble encephalitis lethargica in any essential respect.

CHAPTER XVIII

STOMATITIS AND DIARRHEA OF INFANTS

THIS CONDITION, probably due to a virus related to herpes febrilis, has been described by American workers (Buddingh and Dodd, 1944, Buddingh, 1946, Dodd, 1946). The following account is largely taken from that of Buddingh (1946).

Clinical Features

The highest incidence of attack is in those under 6 months of age. Children over 7 months usually show only stomatitis The onset is sudden, and vesicles develop on the tip and under surface of the tongue, and occasionally on the gums and inner surfaces of the lips The stomatitis persists for 7–14 days, with a tendency to show short periods of remission Young infants are more likely to exhibit diarrhea as the main symptom, the stomatitis being often overlooked The loose stools continue for 4–10 days.

Epidemics may occur in nurseries These epidemics are usually mild, but may be severe, especially in premature babies. Dodd (1946) described an outbreak with a death rate of 50 per cent. Adults in close association with the disease may be affected with stomatitis.

The virus has been recovered from the vagina of mothers of infants who develop diarrhea shortly after birth. The virus has been recovered also from urethral discharge, conjunctivae, and the mouth in a case of Reiter's disease

Pathological Features

Gross changes are found primarily in the small intestine. The mucosa is swollen and shows numerous petechiae. There is ulceration and some cellular infiltration The lesions of the tongue show focal necrosis, and an inflammatory reaction.

Epidemiology

Adults suffering from stomatitis, or without clinical evidence of infection, who harbor the virus, may be the origin of nursery epidemics. The virus can also be acquired during birth from the maternal passages It appears possible that the virus is spread in adults venereally.

Properties of the Causal Agent

The causal agent can be found in swabbings from mouth lesions or in stools, or in the vagina of mothers

Animal experiments Rabbits inoculated on the cornea develop a cloudy opacity in 24 hours The conjunctiva is swollen also, iritis may occur The condition clears up in 2–3 days

Strains of the agent have been maintained by serial passage of ground corneae at 48-hour intervals in young rabbits Histologically there is necrosis and an acute inflammation No inclusions can be seen

Diarrhea can occasionally be produced by feeding infective material to young rabbits The mucosa of the jejunum and ileum shows numerous scattered petechiae.

Local reactions can be produced by scarification or intracutaneous inoculation of the pads of guinea-pigs' feet The lesions show necrosis and infiltration with polymorphs

Filtration The agent is filtrable through Berkefeld V candles.

Eggs. It cannot be transmitted to fertile eggs

CHAPTER XIX

FOOT-AND-MOUTH DISEASE IN MAN[1]

NUMEROUS CASES of foot-and-mouth disease have been described in man (Siegel, 1891, Bertarelli, 1908, Pape, 1921; Fahr, 1923, Trautwein, 1929–30, Fessler, 1934, Curschmann, 1938, Kanyó and Oláh, 1938, Richter, 1938, Rochaix and Delbos, 1938 *a*, *b*, *c*, and *vide infra*). In addition, various authors have published general reviews, often with bibliographies (McBride, 1869, Bussenius and Siegel, 1897, Gins and Krause, 1923–4, Arkwright, 1928, Sée, 1934)

It is probable that many of the recorded cases were not true infections due to the virus of foot-and-mouth disease However, there is a number of cases recorded where the virus has been isolated from the patient, or where the convalescent serum has shown a rise in specific antibody (Flaum, 1939, Bojlén, 1941).

Clinical Features

Incubation period The incubation period is usually from 2 to 5 days, but may be longer.

Onset The patient is usually quite ill, with headache and pyrexia The mucous membrane of the mouth feels dry and hot, and hypersalivation occurs. The skin may be itchy

Course. After a day or so these invasive symptoms subside and the characteristic vesicles appear in the mouth, and sometimes elsewhere (*vide infra*) The lesions a 2 to 3 days t with under- r ! om lasts for more than 8–15 days

Site of the lesions.

Buccopharyngeal cavity The characteristic vesicles are freely distributed on the mucosa of the lips and gums, tongue, and pharyngeal walls, and may attain considerable size before ulceration occurs The tongue and lips are often considerably swollen and painful The effect of these lesions is to provoke salivation, which may be so intense as to cause serious discomfort to the patient. The pharynx is often acutely inflamed and ulcerated, rendering swallowing painful and difficult The breath is usually offensive.

Limbs Vesicles occur in the greatest numbers on the tips of the fingers on the volar aspect, and at the base of the nails (Clough). Another characteristic site is between the fingers, and the lesions may also occur between the toes In severer cases the forearms and legs may also be affected

Other sites A number of authors have noted the presence of lesions on the conjunctivae The eyes have usually been very watery, and the lids gummed together

Histology of the Vesicle

The histology of the vesicle has been well described by Sutton and O'Donnell (1916), and the changes are as follows The cornified layer is parakeratotic, while

[1] Foot-and-mouth disease is predominantly an animal condition Consequently, we shall restrict our description to cases of human infection The properties of the virus are only briefly discussed

Immunity

In human cases, specific neutralizing antibodies develop in convalescence.

On recovery from keratitis, the rabbit's cornea becomes resistant to reinfection in about 3 weeks.

Specific neutralizing antibodies develop in the serum of rabbits immunized by intravenous injection.

the stratum lucidum is thickened and spongy. The cells of the rete malpighii are swollen and increased in numbers, many containing fluid material The vesicle is developed in the deeper layers of the rete; it is somewhat irregular in outline, and is subdivided into loculi by septa. The basal cell layer is almost obliterated, while the prickle cells are infiltrated with fibrin and leukocytes.

Epidemiology

Geographical distribution. Human cases of foot-and-mouth disease have been reported most frequently from Germany. Thus, Bussenius and Siegel (1897) referred to 600 supposed cases in man between the years 1887 and 1894. It is doubtful, however, whether the condition is so common at the present time, although there have been many further descriptions of cases Cases have been reported from the following countries e g., the United States (Clough, 1915, Sutton and O'Donnell, 1916, Sutton and Sutton, 1935), Hungary (Mollow and Pentschew, 1930, v Scheitz, 1934); France (Cadiot, 1913; Sée, 1934; Cambessédès, 1935), Switzerland (Roch, 1939); Scandinavia (Flaum, 1939; Kling, Huss, and Olin, 1939; Bojlén, 1941), Poland (Dlugosz, 1943) In England a number of cases have been described (McBride, 1869, Gibbons, 1924; Dlugosz, 1943). A case has been recorded from the Belgian Congo (Gillain, 1936).

Spread Man can become infected with the virus in various ways. The infection can be spread directly, through contact of the abraded skin with infected animals or their saliva or urine. In these cases the virus usually enters through the skin of the hands, most readily through cuts and abrasions The virus is not of high infectivity for man, and cases in experimental stations are very unusual, despite the risk of contamination of the hands.

The virus may also enter the body by the digestive tract. The usual source of infection in these cases is milk, butter, cheese, or other milk products coming from diseased animals

Fomites may also play a part in the spread of infection

Isolation of the Virus from Human Cases

The diagnosis can be made quite simply by withdrawing vesicle fluid in a capillary tube, and inoculating experimental animals, especially guinea-pigs on the pad (Pancera, 1922, Gerlach, 1924, Trautwein, 1929–30, Fessler, 1934; v Scheitz, 1934, Richter, 1938). It is said that better results are obtained if the ground-up vesicle wall can be used for inoculation, instead of fluid (Bojlén, 1941) On recovery from infection the animals can be "challenged" with known antigenic types, so as to ascertain the infecting type Cattle may also be infected with human material (Bertarelli, 1908, Pancera, 1922)

Serology

The serum of convalescents fixes complement in the presence of a suitable antigen, e g., vesicle fluid, or infected animal tissue (Kanyó and Oláh, 1938) A virus neutralization test can also be performed Serum for these tests should be taken 10–20 days after onset

[illegible] et of pyrexia, [illegible] the conjunc- [illegible] The lacrimal caruncle is usually swollen and shows small Koplik-like spots (*vide infra*), which may also occur on the plica semilunaris (Herrman). Brownlee has stressed the diagnostic value of swelling of the lower palpebral conjunctiva.

4 *Koplik's spots.* These lesions, described by Koplik of New York in 1896, are one of the best known of the prodromal manifestations. They occur on the buccal mucosa of the lips as bright red spots, with a central bluish-white streak, appearing primarily opposite the first molar teeth. They vary from a half-dozen to sufficient to cover the whole of the buccal mucosa With the onset of the rash the spots be- [illegible]

[illegible] fore the rash 47 36 per cent. of patients showed the spots, 2 days before 73 per cent., and 1 day before, they occurred in 100 per cent of cases The spots may occur in the colon (Hobson, 1940, Corbett, 1945).

5. *Pharyngeal signs* During the early stages of invasion the fauces appear red and the soft palate, uvula, and posterior pharyngeal wall show scattered red-brown spots. Herrman (1914, 1915) has drawn attention to tonsillar spots, which he found in 40 per cent. of cases They occur as bluish-gray to white spots varying in size from a pin point to a pin head

6 *Prodromal rashes.* These rashes have been described by various authors (e g, Adkins, 1899, Rolleston, 1905, Stimson, 1928). They may occur on the first day or so of the fever as fine macules, papules, urticarial lesions, scarlatiniform spots, or blotchy erythemas. They are to be found in 30–50 per cent. of all cases Rolleston (1905) mentions the following characteristics of these rashes

(*a*) They appear early, within the first 2 days of the disease, and frequently before Koplik's spots, thus having great diagnostic value.

(*b*) The erythematous and urticarial lesions are transient and may only last for a few hours, although the scarlatiniform, macular, and papular rashes last for a day or more.

(*c*) The distribution is localized, but there is no elective site, and any part of the trunk or limbs may be involved, the face and neck are rarely affected

(*d*) The spots are polymorphic, lesions such as macules and papules may occur together.

(*e*) The rash is not painful or itchy.

7 *Catarrh* The eyes are usually "running" and the conjunctivae suffused. Rhinitis, pharyngitis, bronchitis, and enteritis all commonly occur. Mayerhofer (1932, 1934), in particular, has stressed the diagnostic value of angina in the prodromal period Laryngitis may develop in the preeruptive stage and lead to confusion with diphtheria Box (1933) has described a suffocative catarrh which may develop prodromally, the temperature is raised, the child coughs, is dyspneic and cyanosed, and expectorates profusely, the mortality rate is high. The tympanic membrane may be congested and there may be earache (see Bespaloff, 1937).

Course of the Disease

After 3 to 4 or more days during which prodromal symptoms have been noted, the characteristic rash and other manifestations appear The rash may be delayed in its appearance, and Selby (1936) has recorded cases in which it was noted 9 and 11 days after the onset of prodromal symptoms

The rash.

Many excellent descriptions of the well-known rash are available and the features need only be summarized here (see, e g, Rolleston, 1929) Most frequently

CHAPTER XX

MEASLES (MORBILLI)

THE CONTROL of measles by ordinary public health measures has proved a notable failure, but a powerful prophylactic method has been available for some years By injection of immune measles serum and other biological products it is now possible to prevent cases of measles The fact remains, however, that such measures have not seriously lowered the incidence of the disease, which still remains a major problem to public health administrators. With regard to literature, the work of Thomson and Thomson (1931)[1] is by far the most complete and should be consulted by those desiring further references Other general reviews have been published (McCartney, 1927; Rolleston, 1929, Smith, 1944).

CLINICAL FEATURES

Incubation Period

This is relatively long, about 10 to 12 days, with outside limits of 7 to 21 days (see, e g , Lewy, 1920, Thomson and Thomson, 1931; Stocks, 1931).

The percentage of incubations of 15 days or more was found to be significantly greater in the 12–23 month age group (Stillerman and Thalhimer, 1944).

Illness of infection Goodall (1925) recorded some 7 cases in which children developed pyrexia, sneezing, injection of the conjunctivae, and sometimes a morbilliform rash, within a few hours after contact with a case of measles. After the appropriate incubation period the usual symptoms of measles developed. Erdheim (1926 *b*) made similar observations, noting signs of catarrh several days before the rash Another series of cases was described by Abercrombie (1929) in which some 12 to 13 days before the appearance of the rash children developed fever, gastro-intestinal disturbance, bronchitis, sore throat, and earache Meyer and Greenthal (1930) recorded 4 possible cases of this illness of infection (see also *M.R.C Report*, 1938) The exact explanation of these cases is obscure, but Orel (1925–6) has suggested that the symptoms are due to a mixed infection

Prodromal Symptoms

During the stage of invasion the child is acutely infectious and spreads the disease to numbers of contacts, as isolation is seldom effected until too late The prodromal period may begin at any time up to one week before the development of the rash, although it seldom lasts longer than 3 to 4 days A number of affections occurs in this period which point to the true nature of the illness

1 *Blood* During the early part of the incubation period there is a leukocytosis, which gives place to a prodromal lymphopenia

2. *Pyrexia.* Pyrexia is frequently the first symptom of illness noticed in a child exposed to infection some 10 or more days previously

3. *Eye signs* Changes in the conjunctivae have been stressed by various observers (e g , Koplik, 1896, Herrman, 1914, Brownlee, 1920, Stimson, 1928, 1931) The lower lids appear puffy and there may be a definite congested line across the lower

[1] References are appended at the conclusion of Ch XXII, p 235 et seq

The spleen.

It was suggested by Bleyer (1926) that definite enlargement of the spleen was commonly observed at the time of onset of the rash Friedman (1927, 1931), however, found that this only occurred in 11–12 per cent., was not marked, and appeared independently of the rash.

The sympathetic system.

By studying the oculo-cardiac reflex Lavergne and Debenedetti (1931) noted a sympatheticotonia at the onset of the rash. With the development of the eruption vagotonia supervened, and then there was a return to normal

Varieties of Measles

Morbilli sine morbilli and morbilli bullosi have already been referred to, measles without any catarrhal symptoms (morbilli sine catarrho) may also occur. Rolleston (1929) described the following 3 additional varieties hemorrhagic, ataxodynamic, and suffocative Hemorrhagic measles is very rare and is said to be characterized by bleeding from the lung, bowel, stomach, and other sites (Baker, 1941, Linehan, 1942). Ataxodynamic measles is characterized by hyperpyrexia, delirium, and prostration Suffocative measles presents from the start the picture of a severe dyspnea without any chest signs (see Nobécourt and Lereboullet, 1931; Box, 1933) This type of affection is usually evident about the second day of the rash, the patient is dyspneic and cyanosed, and coughs and expectorates profusely, these cases are usually fatal.

CROSS INFECTION IN MEASLES

Measles virus appears to predispose the respiratory tract to invasion by pathogenic bacteria. When patients are nursed in "open" wards there are abundant opportunities for cross infection of the upper respiratory tract with the subsequent development of bronchitis, bronchopneumonia, and especially otitis.

The main secondary invader is the hemolytic streptococcus, and Allison and Brown (1936) found 51.2 per cent. of patients to be so infected

This question of cross infection in measles wards has been extensively investigated by a group of workers in London fever hospitals. Thus, Wright, Cruickshank, and Gunn (1944) found the predominant organism in ward dust to be a Type 6 hemolytic streptococcus This organism accounted for over 90 per cent. of cross infections, and all the late otitis cases. They showed that the oiling of floors alone did not reduce the incidence of cross infection with the streptococcus When bedclothes and garments were oiled as well, the cross infection rate dropped to 18 6 per cent, as compared with 73 per cent in a control "unoiled" ward In the control ward, 14 3 per cent. of patients developed otitis due to Type 6 streptococcus, whereas in the oiled ward the incidence was only 2 8 per cent. In a later study, Wright (1945) found that 72 per cent of 65 patients at risk acquired infection with Type 6 hemolytic streptococcus, 44 7 per cent. of the cross infections occurred within 1 week, and 34 per cent. in the second week of hospitalization

It now appears that the conditions favoring secondary infection with hemolytic streptococci vary from year to year For example, Begg, Smellie, and Wright (1947), working at a later date, in another London fever hospital, found the incidence of streptococcal cross infection in an "oiled" ward (12–20 per cent.) almost exactly the [illegible]
was very lo[illegible]
cocci differ[illegible]
Type 6 was rarely found, but other A types, and members of Groups C and G were responsible

The question of control of cross infection is discussed below

the rash appears first behind the ears, and within 24 hours spreads to involve the face, head, and neck; the arms, trunk, and legs are soon involved also. The measles papule is very often crescentic, and the individual lesions usually remain discrete, although confluent patches may be found After 3 to 4 days the rash begins to fade, leaving a brownish discoloration and "branny" desquamation. It is well known that the rash may appear most profusely in the neighborhood of various sources of irritation or skin disease, thus Aitken (1933) has shown that the rash may appear markedly on an area of pigmentation due to ultraviolet radiation.

Morbilli sine morbilli This name is given to cases of noneruptive measles; the patient shows catarrh, Koplik's spots, fever, and prodromal rashes but no typical measles eruption (Rolleston, 1904).

Morbilli bullosi. Bullous eruptions may develop shortly after the first appearance of the rash (see Neff, 1920, Burdick, 1922). Thus, Morton (1921) described a case in which after 24 hours bullous eruptions appeared and spread from the chest to the face, trunk, and limbs, he referred to approximately 20 similar cases.

Kelleher (1933) reviewed various reported cases of morbilli bullosi and considered there were good grounds for regarding them merely as acute pemphigus, and not measles at all. In many of the cases, for example, there were no Koplik's spots, further, many patients had already had a genuine attack of measles Ronaldson (1937) formed the opinion that the reported cases fall into 3 groups·

(*a*) True pemphigus with a morbilliform eruption, such cases not being measles at all

(*b*) Genuine cases of measles with an anomalous eruption, i e, true morbilli bullosi (see also James and Miller, 1938)

(*c*) Measles and pemphigus may coexist.

Pyrexia.

Stimson (1928) has given the following description of the various types of temperature chart that may be found in measles

(*a*) *The typhoid type.* Fever is noted in the prodromal period as the first manifestation of illness The temperature rises steadily, so that after 4 to 5 days and with the appearance of the rash it has reached about 104° F

(*b*) *The malarial type* In this type there is fever for the first day or so of the prodromal period, followed by a return to normal for a short space, with a subsequent rise (see also Paton, 1932)

(*c*) *The severe type.* This reaction is frequent in pneumonic cases, when the temperature rises quickly at the start to about 103° to 104° F. and remains raised throughout the prodromal period

(*d*) *The modified type* This type of reaction is seen in those treated prophylactically with serum (sero-attenuation) The temperature gradually rises to 101° to 102° F and slowly falls again

In all types the temperature usually falls by crisis or rapid lysis when the rash is well developed, any subsequent rise probably indicates the onset of a complication

Catarrh.

The prodromal catarrh is usually considerably aggravated with the advent of the rash. The larynx may be involved during the eruptive stage giving hoarseness, cough, and perhaps loss of voice (see Oliver and Turner, 1933) The child is usually "running" at the eyes and "streaming" at the nose, enteritis is common Certain important complications in the ear and respiratory system may develop (*vide infra*).

son (1931) examined 75 cases by lung puncture. In 46 per cent. of cases influenza bacilli were isolated, in 28.4 per cent. *Pneumococcus*, in 8 per cent. *Streptococcus hemolyticus*, in 4 per cent. *Streptococcus viridans*, and in 11 per cent *Staphylococcus* and *Micrococcus catarrhalis*. Ellison found that the influenzal type of case was distinguished by a very severe toxemia and heliotrope cyanosis

The hemolytic streptococcus has figured more prominently in other series Thus, it was the causal agent of the epidemic of postmeasles interstitial bronchopneumonia described in the United States by Cole and MacCallum (1918). Thursfield (1912–13) found the *Streptococcus hemolyticus* in just over 50 per cent of cases, *Pneumococcus*, *Staphylococcus aureus*, and influenza bacilli constituting most of the remainder. Ritossa (1938), in Rome, found the *Pneumococcus* the commonest organism in respiratory complications

Other respiratory complications.

Lobar pneumonia may sometimes occur. Degen (1937) found empyema in 13 per cent. of autopsies and fibrinous pleurisy in 14 per cent.

2. Central Nervous System

Cases of encephalomyelitis during an attack of measles have been reported by numerous authors (e.g., Benn, 1931; Bernuth, 1928–9, Bregman and Poncz, 1929, Bourne, see Winnicott and Gibbs, 1926, Bridgeman, 1937, Crockford, 1932, Draganesco and Milcoveanu, 1936, see *New Zealand Medical Journal*, 1936, Genoese, 1932, Greenfield, 1928–9, Jenkins, 1929, Lancaster, 1938, Miller, 1931, Neale and Appelbaum, 1927, Parrish, 1936, Peterman and Fox, 1933; Price, 1937, Rosenheck and Barowsky, 1937, Signa, 1929, Sulzer, 1930, van Bogaert, Borremans, and Couvreur, 1932; Chinner, 1940, Geiger and Sappington, 1940, Burton and Weir, 1941, Schaffer, 1941, Litvak, Sands, and Gibel, 1943, Meyer, 1943, Reisman and Rosen, 1943). General reviews of the subject have also appeared (Ford, 1928, Greenfield, 1929, van Bogaert, 1933).

Ford reviewed 113 cases and described 12 from his own experience. Since that time there has been no lessening of interest in the subject, and the number of published cases must now number some hundreds The following account is largely based on that of Ford

Clinical features This complication usually develops as the rash begins to fade, although the onset may be earlier, even in the prodromal stage (Arena, 1946). The temperature rises, and the patient becomes drowsy; rigidity and convulsions are common Mild cases recover rapidly, but sometimes severer symptoms may occur· e g, tremors and other signs of neuromuscular incoordination; paraplegia or hemiplegia, purely meningitic symptoms (Tuà, 1923, Reiche, 1927, Lioret, 1930), the cerebellar syndrome (see, e g, Cole, 1938), myelitis (Babonneix and Lévy, 1931, Miller and Ross, 1931, Kousmine, 1934, Rosenheck and Barowsky, 1937, Ward, 1941, Rydeen and Glaser, 1942, Pearlman and Shirreff, 1944), loss of urinary and rectal sphincter control (Miller and Ross, 1931, Elliott and Elliott, 1933, Barnes *et al*, 1937), multiple peripheral neuritis (Urquhart, 1934, Mohammad, 1936, Lenègre and Delair, 1939)

The cell count of the cerebrospinal fluid is usually raised up to about 200 per c mm lymphocytes, while globulin is definitely increased McCausland and McClendon (1934) carried out encephalography, finding dilated lateral ventricles and an increase in the subarachnoid air spaces As regards prognosis, the mortality varies from 10–30 per cent, about 40 per cent recover completely and 40 per cent. recover with sequelae (Ford, 1928, Norman, 1936, Ford and Guild, 1937, Hamilton and Hanna, 1941, Smith and Trapp, 1944) Stitt (1943) described an interesting case where the symptoms were definitely aggravated by smallpox vaccination

Pathology. The pathological features have been described by numerous authors (e g, Barlow and Penrose, 1886, Wohlwill, 1928, Greenfield, 1929, Walthard, 1929,

COMPLICATIONS

1. Respiratory

Laryngitis.

The laryngitis of the eruptive stage may produce ulceration of the arytenoid cartilages and the vocal cords (see, e.g., Box, 1933). In 13 per cent. of measles autopsies Degen (1937) found evidence of laryngeal ulceration, membrane formation, or obstruction. Edema of the glottis or larynx is usually fatal (Homrighouse and McKee, 1939; Mulvaney, 1942).

Bronchopneumonia.

Bronchopneumonia is the most dreaded complication of measles, especially in young children (see Box, 1933). Thus, in the 1927–8 London epidemic 86 per cent. of all measles deaths in the Metropolitan Fever Hospitals were due to pneumonia (Ellison, 1931). In 100 autopsies Degen found evidence of bronchopneumonia in 96. Below the age of 2, from 30 to 50 per cent. of cases of bronchopneumonia die (see, e.g., *Chevalley, Duchon, and Forestier, 1936*). The disease was very prevalent in the United States in soldiers in World War I (see Cole and MacCallum, 1918).

The disease may develop early, or during the eruptive period, other cases develop later, the eruptive fever falling only to rise again with the onset of bronchopneumonic complications.

Pathology. The pathological features of measles bronchopneumonia have been described by various authors (e.g., by Cole and MacCallum, 1918, Denton, 1925, Kuraya, 1929, Ellison, 1931, Smith, 1931, Box, 1933, McCordock and Muckenfuss, 1933, Moore and McCordock, 1934, Degen, 1937, Milles, 1945).

Naked-eye, the lungs are congested and usually show patches of reddish or gray consolidation, bronchopneumonic in distribution. The larynx, trachea, and bronchi are congested and may contain mucopurulent secretion.

Microscopically a variety of changes may occur, in many cases resembling closely the acute bronchopneumonia of influenza (see Ch. LV). Thus in some the picture is that of a pure virus pneumonia (e.g., Moore and McCordock's and Kuraya's cases). The red patches observed naked-eye prove to be necrotic areas where red cells are present in the alveoli and bronchioles. There is only scanty inflammatory reaction.

In other cases the picture is more of a peribronchiolitis with interstitial inflammatory changes. The interstitial tissue is swollen and infiltrated with a serofibrinous exudate. All coats of the bronchioles are inflamed, swollen, and infiltrated with leukocytes, the lining membranes are usually desquamated and the lumina contain mucopurulent exudate. There are areas of peribronchiolar pneumonia where the alveoli are filled with a fibrinopurulent exudate. The infection spreads throughout the parenchyma from these peribronchial nodules.

The changes in the lung are, of course, the most important, but cellular infiltrations and degeneration occur in the mouth, pharynx, larynx, and bronchial passages as well. During the acute stage mediastinal and subcutaneous emphysema may develop. If the child recovers, there is a strong tendency for fibrosis, often with bronchiectasis, to follow.

Giant cells, described as of the nonspecific fused respiratory epithelium type, may be numerous in the bronchi and bronchioles (Stryker, 1940, Corbett, 1945, Milles, 1945, Pinkerton, Smiley, and Anderson, 1945, Archer and Biggs, 1947).

Bacteriology. The bacteriological findings in measles bronchopneumonia are somewhat complex. In certain cases, undoubtedly, the condition is a virus pneumonia in which the virus has shown an unusual tendency to invade the lower respiratory tract. *In other cases the rôle of cultivable organisms* has been established, and these are probably invaders acting secondarily to the virus. Thus, Elli-

schitsch, 1927; Asherson, 1932; Allison and Brown, 1936, Wright, Cruickshank, and Gunn, 1944, Wright, 1945).

Otitis occurring before the 5th hospital day is not regarded as being due to cross infection, but later cases, developing on and after the 6th day are believed to be so explained. Late otitis is about 4 times as frequent as early otitis The great bulk of otitis cases are due to hemolytic streptococci. At one time in London, Type 6 was very prevalent, and about 1 patient in 5 developed otitis Later this type became much rarer, and the incidence of otitis was only 1/376 cases (see above). Wright (1945) reported that late otitis was much less common in April and May than in December–March

4. Appendicitis

In 1936 Hudson and Krakower reviewed some 31 cases of measles with appendicitis and added 9 from their own experience In 15 cases the appendicitis occurred prodromally, in 12 in the eruptive stage, and in 13 in early convalescence Degen (1937) found 3 cases of appendicitis in a series of 100 autopsies. Later cases have been described by Koch (1937).

A number of authors has recorded the presence of multinucleate giant cells in appendices removed in the p [illegible] berg, 1932; Finkeldey, 1932, Ve [illegible] Hudson and Krakower, 1036, [illegible] the same type as those found [illegible] *infra*), measuring about 100 μ and containing 70 to 100 nuclei arranged centrally.

5. Skin Complications

Apart from morbilli bullosi already discussed, certain other skin complications may develop For instance, a cold urticaria was recorded in 3 sisters by Kobacker and Parkhurst (1935; see also Apert and Broca, 1923). Purpuric lesions have also been reported (see, e g, Kelly, 1922, Laurent, 1933)

6. Other Complications

The following is a list of other complications that may occur. stomatitis, noma of the cheek or pudenda, tonsillitis, [illegible] (Binder, 1931), tetany (Ghosal, 19 [illegible] corded a temperature of at least 110° [illegible] rene (Rolleston, 1925–6, Winstead, [illegible] a series of 100 autopsies Degen (1937) found pericardial effusion in 13 per cent of cases and pericarditis in 4 per cent, also peritonitis in 5 per cent.

CLINICAL PATHOLOGY

The urine frequently gives the diazo reaction 2 to 4 days after the appearance of the rash (Malmberg, 1922–3)

The serum may give nonspecific positive reactions in the Wassermann and Meinicke tests (see Pockels, 1931). Mineral phosphorus is said to be diminished at the onset of the rash to 1 8 mg. per cent, but after 2 to 3 days the level returns to normal (Lesné, Zizine, and Briskas, 1934) Plasma amino-acid nitrogen concentration is usually within the normal range (Farr, McCarthy, and Francis, 1942)

There is a mild leukocytosis during the early part of the incubation period, during the prodromal period there is lymphopenia with relative neutrophilia (Stimson, 1928, Lane, 1930, Benjamin and Ward, 1932, Manson, 1935) At the height of the illness there is a general leukopenia, while during convalescence a lymphocytosis may be noted The appearance of the blood changes may be prevented by the use of immune serum (Gunn, 1942)

The red cells are said to be reduced to about 4,000,000 per c.mm. during the

1930, 1937; Zimmerman and Yannet, 1930, Wilson, see Benn, 1931, Ferraro and Scheffer, 1931, 1932; Erb and Morgan, 1933; Marsden, 1934; Babonneix, Lhermitte, and Trelles, 1934; Moore and McCordock, 1934; Degen, 1937, Finley, 1937, Malamud, 1937, 1939, Ziskind and Schattenberg, 1939, and see Greenfield's article for a full bibliography).

(*a*) *Vascular lesions.* Diffuse congestion and petechial hemorrhages are frequently seen by the naked eye in the cerebral white matter, basal ganglia, midbrain, and pons Microscopically, perivascular hemorrhages and edema may be observed, especially in the pons, these changes being found in the majority of cases. Thrombosis and vascular endothelial swelling have also been reported (Ferraro and Scheffer, 1931).

(*b*) *Perivascular cuffing* The commonest infiltrating cell is the lymphocyte, although fat granule cells and plasma cells may also occur Perivascular cuffing is a variable feature, being more prominent in some reported cases (e g, those of Greenfield, Walthard, 1930; Ferraro and Scheffer, 1931) than in others (e g, those of Wohlwill, Moore and McCordock, Marsden).

(*c*) *Demyelination.* Many of these reported cases showed demyelination widespread in the brain and cord (e g, the cases of Greenfield, Wohlwill, Finley, Moore and McCordock, Zimmerman and Yannet, Marsden, Malamud). Wohlwill made a special study, and found that demyelination occurred under the spinal pia, subependymally and perivenously throughout the central nervous system. Perivascular demyelination was most pronounced in the subcortical white matter of the superior and posterior parts of the cerebrum. Greenfield's case showed demyelination to be most pronounced around medium-sized vessels in the deeper parts of the centrum ovale In Moore and McCordock's case the dorsal border of the corpus callosum and the cervical cord were chiefly involved. The demyelinated areas were usually infiltrated with polymorphs and mononuclears, and there was a reactionary perivascular microgliosis Other authors have reported similar appearances

(*d*) *Nerve cells* With regard to the nerve cells, these are usually more or less normal, although slight degeneration may be noted Ferraro and Scheffer (1932) described a case which differed from the usual type of postmeasles encephalomyelitis in that no demyelination was seen, but there was a pronounced involvement of the gray matter There was a diffuse and acute swelling and degeneration of nerve cells in all parts of the cortex and central masses They likened the appearances to those of lead poisoning

Etiology The most constant histological findings are congestion, hemorrhages, and perivascular demyelination, perivascular cuffing is inconstant. The changes are identical in kind, therefore, with those of the commoner postvaccinal encephalitis, they differ slightly in degree, however Thus, Greenfield states that in postvaccinal encephalitis there is a greater amount of perivascular infiltration and more complete demyelination

It is evidently impossible to discuss the etiology of measles encephalomyelitis as an isolated condition, it must be considered together with postvaccinal encephalitis and that of related conditions (see Ch XXXV) Although Gay (1932) isolated the herpes virus in 3 cases, it is generally held that the condition is due to the measles virus This supposition has been confirmed by Shaffer, Rake, and Hodes (1942) who isolated measles virus from the brain of a 7-year-old boy by inoculation in *M. mulatta* We would suggest that this agent is one of many which cause intravascular thromboses in the central nervous system with resultant demyelination

3. Otitis

Measles is responsible for many cases of otitis media, sometimes giving rise to permanent deafness and its usual accompaniments One may expect from 13–20 per cent. of measles cases to be complicated by otitis (Gardiner, 1924, Urbant-

all measles deaths in fever hospitals were due to pneumonia (Ellison, 1931). In 100 autopsies Degen (1937) found 96 cases of bronchopneumonia The main secondary invader in these cases is undoubtedly the hemolytic streptococcus.

2. Most deaths occur in those under 5 years of age, and especially under 3 years. Halliday (1928) stated that, taking measles mortality from 5–10 years as unity, then from 0–2 years the mortality is 10–20 times greater, from 2–3 years 8–11 times greater, from 3–4 years 3½–4½ times greater, and from 4–5 years 1½–2 times more than unity.

3 Mortality is affected by a number of factors other than age Thus rickets has been incriminated as a factor tending to increase
nutrition in general is a factor. Measles devel
from other diseases is frequently fatal In New
death rate among Italian children, while thos
lowest rate. The winter fatality is about double that of the summer.

4 Perhaps the most important of these other factors is housing Halliday (1928) showed that in tenements in "slum" areas, children are exposed to infection at an earlier age than are those in new housing estates. Accordingly, in slum areas, measles is a disease of infancy, whereas in more "residential" areas school children are the main victims The children of the well-to-do tend to be infected later still, from 14–18. Many similar observations have been made. Thus in France, Debré and Joannon (1924) found that the mortality from measles under 6 years was 4 times greater in the poorest than in the richest districts Godfrey (1926), in America, found that 18 per cent. of cases and 83 per cent. of deaths occurring in the towns were in children under 3, whereas in the villages there were 11 per cent of cases and 61 per cent of deaths for this age group Picken (1921) found that the fatality rate per 100 cases in urban districts was 6 1 per cent, and in rural districts about 1 to 1 3 per cent. He showed that the incidence of the disease in one-apartment houses was 1 85 per cent, in three-apartment houses 0 69 per cent., and in larger houses 0 31 per cent. Wright and Wright (1942), investigating this problem in London, concluded that Halliday's observations seemed equally applicable. They found that statistically, substandard housing was the predominant social factor in mortality.

5. In Great Britain, the deaths from measles are now only a fraction of formerly—less than 1,000 per epidemic year The case fatality rate is about 0 2 per cent. A similar decline in the death rate has been noted in the United States, Canada, and elsewhere (see McKinnon, 1948)

McKinnon suggests that a partial explanation is the reduction in physically substandard children

Butler (1945, 1946, 1947 *a*) has discussed this problem, and it may be concluded that various factors are responsible (*a*) Greater care of the sick in the home, (*b*) hospitalization and improved treatment of severe cases, (*c*) an increased incidence on the more resistant older child as compared with earlier days, (*d*) an improved state of nutrition in childhood, (*e*) perhaps a less severe type of infection

Butler (1945, 1947 *b*) has made use of the batch fatality rate, which as far as possible relates deaths to the actual cases from which they derive. Where serial cases and deaths are recorded week by week, the batch fatality rate at the terminal week of each successive 9-weekly period is

$$\frac{\text{the sum of deaths in last 5 weeks} \times 1{,}000}{\text{Half the sum of the cases of the first 4 weeks} + \text{all the cases of the middle week} + \text{half the sum of the cases of the last 4 weeks}}$$

PATHOLOGY OF UNCOMPLICATED MEASLES

1 *Koplik's spots.* These lesions usually originate in a submucous gland, there is focal necrosis of the basal epithelium, and formation of a vesicle with exudation of

preeruptive stage, the color index being about 0 6 to 0 7 owing to a fall in hemoglobin (Schiff and Mátyás, 1918–19 *a*, Stancanelli, 1934).

During the eruptive period Kasahara and Maeda (1931–2) found an increase in reticulocytes, evidently indicative of some blood cell destruction The bleeding time was found to be shortened (Schiff and Mátyás, 1918–19 *b*).

The opsonic index has been examined, and Tunnicliff (1912) reported a decreased phagocytic activity for *Streptococcus*, *Staphylococcus*, and *Myco. tuberculosis* during the leukopenic stage. The opsonic index was also investigated by Piana (1930), who found it to be frequently lowered for *Bact. typhosum*, normal for *Br. melitensis*, and (contrary to Tunnicliff) increased for *Streptococcus*

Radiography of the chest. Radiological examination of the chest during the progress of measles was carried out by Kohn and Koiransky (1929, 1931, 1933) in a considerable number of cases Under 4 years of age 62.4 per cent. of patients showed shadows indicative of pulmonary infiltration, while over 4 years some 42.2 per cent showed these shadows. These markings were usually evident before or during the eruptive stage. Further, in the majority of cases, they found enlargement of the lymph glands in front of and below the bifurcation of the trachea This enlargement was usually maximal at the height of the eruption As these cases were unselected it shows that pulmonary involvement is a frequent occurrence in measles These results were substantially confirmed during the 1935–6 London epidemic (see *Report*, 1938).

DISTRIBUTION OF THE VIRUS IN THE INFECTED BODY

Blood. The virus probably occurs in the blood shortly before the appearance of the rash, and persists for at least 24 hours, as shown by infectivity for human volunteers, monkeys, rabbits, guinea-pigs, and eggs (Nicolle and Conseil, 1911, Anderson and Goldberger, 1911 *a*, Hektoen and Eggers, 1911, Tunnicliff, 1912, Kawamura, 1922, Degkwitz, 1927–8, Belikoff *et al.*, 1929, Taniguchi *et al*, 1935, Plotz, 1938 *a*, *b*, Rake and Shaffer, 1939, 1940, Gordon and Knighton, 1941, Hurst and Cooke, 1941, Shaffer *et al*, 1941, Rake, 1943, Konova *et al.*, 1945) Hektoen (1905) reproduced measles in a volunteer with blood taken 30 hours after the appearance of the rash Papp (1937) has claimed that the virus is associated with the leukocytes and not the plasma It should, however, be mentioned that despite the above results certain workers have found blood noninfective for monkeys, even early in the eruptive phase (Sellards, 1919 *a*, *b*, Sellards and Wentworth, 1919).

Mucous secretions. Buccal, pharyngeal, and nasal secretions are infective for monkeys, tissue cultures, and eggs in the preeruptive stage, and up to 48 hours after the appearance of the rash (Goldberger and Anderson, 1911 *a*, Anderson and Gold- … , Tunnicliff and Moody, 1922, Degkwitz, … and Shaffer, 1939, 1940, Hurst and Cooke, 1941, Rake, Shaffer, and Jones, 1941, Konova *et al*, 1945)

The eruption Mayr (1852) claimed to have infected children by nasal inoculations of scrapings from the rash Torres and Teixeria (1932 *a*) produced a rise of temperature and leukopenia in monkeys after injection with morsels of the exanthem Measles scales have been found noninfective for children (Mayr, 1860) or monkeys (Anderson and Goldberger, 1911 *b*)

MORTALITY

Measles ranks high among the main killing diseases of childhood, and this question has received attention from a number of writers (MacNalty and Wheaton, 1918, Brownlee, 1920, Halliday, 1928, Fischl, 1929, Soper, 1929, Godfrey, 1926, Degen, 1937, Brincker, 1938; Butler, 1945, 1947 *a*, *b*)

1. Most deaths occur after the first week, usually in the second or third, and are due to respiratory complications Uncomplicated measles is only rarely fatal (Wilson, 1928–9) For example, in the 1927–8 London epidemic, 86 per cent of

Koplik's spots, the nasal mucosa, and the blood monocytes. These vary in size and are found in the cytoplasm, staining with nigrosin. With regard to intranuclear bodies, Torres and Teixeria (1932 *b*) have described equatorial bands in the nuclei of the stratum granulosum and superficial malpighian layers These structures probably consist of a condensation of nuclear material.

5. *Other features.* In Degen's (1937) series of 100 autopsies certain pathological findings, scarcely to be regarded as complications, were reported Thus, the tonsils were often enlarged and inflamed, Alagna (1911) found giant cells in the tonsils in fatal cases The lymph glands were also enlarged and showed subacute inflammatory changes The spleen was frequently enlarged and congested, showing lymphoid hyperplasia The liver and kidneys were also congested and showed cloudy swelling.

It has been remarked that cases of measles coming to autopsy usually show a well-developed complication Wilson (1928–9), however, has reported a case of fatal, apparently uncomplicated, measles Changes were found only in the respiratory system, thus the lungs were congested and exuded blood-stained fluid Microscopically the alveoli were filled with clear pink-staining material and some fibrin and mononuclear cells The mucosa of the mouth, larynx, trachea, and primary bronchi showed pale and swollen epithelium, with a scanty infiltration of round cells and polynuclears. There were some areas of ulceration, beneath which were collections of mononuclear cells

EPIDEMIOLOGY

The Method of Spread of Measles

Epidemiologically it is evident that measles is infective in the prodromal catarrhal stage, and for 2–3 days of the eruptive stage Correspondingly, virus has been isolated from the upper respiratory tract in the preeruptive and early eruptive phase, it has also been found in the eruption. In some cases, infection may be spread by direct or indirect contact with the skin. Much more usually, infection is contracted by inhalation of droplets, and air-borne droplet nuclei are usually held responsible (see Wells, 1944) Larger droplets may also be responsible, as where the sufferer coughs or sneezes in the vicinity of a susceptible person Experiments of Hare and Mackenzie (1946) with *B. prodigiosus* suggest, however, that another mechanism may often be involved They suggest that exhaled particles largely fall downward and adhere to clothing Later, clouds of infective particles may be liberated by shaking the clothing Certainly there are obvious instances where infection by some such means must be invoked, and where there can be no question of droplet nuclei being responsible.

The Incidence of Measles

Age incidence The greatest number of cases of measles, and certainly the greatest number of fatal cases, occur in children under 5 years of age The great majority of adults in civilized lands has suffered from measles Thus, Butler (1912–13), investigating the measles histories of 14,000 persons, found that 78 per cent at all ages had been attacked Analyzed, these figures showed that from 0 to 4 years 8 4 per cent had been infected, while over 15 years some 97 3 per cent had suffered from measles Collins (1924) found that 90 to 95 per cent of American students had been attacked

The disease is rare in newborn infants (up to 5 months) of mothers who have had measles (Herrman, 1917, 1923, Friedjung, 1918–19) Definite cases of measles, both congenital and in the first few months of life have, however, been recorded (e g, by Ballantyne, 1893, Schulze, 1921, Ronaldson, 1926, Purves, 1934, Dyer, 1940, Lyall and Murdick, 1941) At the other extreme of life, cases have been

serum and emigration of endothelial leukocytes, the spot is surrounded by dilated vessels (Hlava, see Ewing, 1909, Denton, 1925). In certain cases the spots may present the ordinary microscopic appearance of the measles exanthem, with superficial parakeratosis or keratosis and later desquamation (Hlava). Inclusion bodies, staining with nigrosin, and occurring in the cytoplasm, have been found by Broadhurst *et al.* (1937, *vide infra*).

2 *Giant cells.* A number of authors has recorded the presence of giant cells in various tissues during the prodromal period (for a general review see Ravina and Lévy-Lang, 1937) Thus, these cells have been found in the tonsil (Finkeldey, 1931, Warthin, 1931, Mayerhofer, 1934), the appendix (references given above), the spleen, thymus, liver, and lymph glands (Hathaway, 1935; Wegelin, 1937, Semsroth, 1939, Schultze, 1943); *oral, throat, laryngeal, bronchial, and esophageal mu*cosae (Masugi and Minami, 1938; Minami, 1938, Homrighouse and McKee, 1939, Semsroth, 1939).

Warthin (1931) fully described the appearance of these cells in the tonsil Beneath the tonsillar surface epithelium is a narrow zone where there are large syn*cytial multinucleated giant cells, measuring about 100 μ. These cells are spherical* or somewhat lobed, the nuclei occurring in a central cluster, numbering up to 70–100, and being frequently pyknotic. Giant cells are also found in and between the germinal centers, and probably develop by amitotic division of lymphocyte-like [illegible] l show marked lymphoid exhaustion Similar [illegible] glands.

[illegible] res of the measles exanthem have been described by various authors (see, e.g , Catrin, 1891; Ewing, 1909, Mallory and Medlar, 1920). Ewing gives a full bibliography. Mallory and Medlar's findings will be described, as these seem to represent the normal.

[illegible] nall [illegible] the epidermis with endothelial leukocytes which may collect to form pustules under the cornified layer, these pustules soon dry up to form a plaque (Ewing's hyper*keratosis*) *Retrograde changes appear as necrosis of epithelial cells which* affects individual or groups of cells Necrosis takes place also in the hair sheaths and sebaceous glands, cells in these areas show cytoplasmic droplets of varying size and shape.

The corium also shows changes, in the superficial layers of the corium and papillae there is an active exudate of endothelial leukocytes, which have mostly developed by proliferation and emigration of vascular endothelium. The cytoplasm of these cells is basophilic, shows a network, and often contains polymorphs or leukocytes. The vascular endothelium in these areas is swollen and the cytoplasm granular. The measles lesion probably starts in and around the superficial vessels of the corium, emigration of endothelial leukocytes occurs and spreads to the overlying epidermis, then small pustules may form which later dry up.

4. *Inclusion bodies* A variety of inclusion bodies has been described in measles, thus Catrin (1891) found large mulberry-shaped masses in the cytoplasm of the epidermal cells, pushing the nucleus to one side. Somewhat similar bodies were found by Ewing (1909), these being irregular, more or less homogeneous basophilic rings, spheres, or crescents occurring in the cytoplasm of the malpighian cells. The bodies described by Catrin and Ewing are probably of degenerative nature Small [illegible] ascular endothelium by Mallory and Medlar [illegible] ively and may have represented phagocyted [illegible] ody-like granules have been recorded by Lipschutz (1926), [illegible] *itrophyten* They measured 0.2 to 0 3 μ in diameter and were found in epidermal cells

Broadhurst *et al.* (1937, 1938) have found granular inclusions in the cells of

inter-epidemic periods in which few cases are recorded. In large countries, composed of numerous units, there is usually an epidemic in progress somewhere or other. In this case compensation between the occurrence of endemic cases and epidemics renders the morbidity and mortality curves more uniform. However, the state of affairs is not always so, because variations in the curves may be quite considerable. In England in the years 1919–30 the maximum death rate recorded was 3½ times the minimum, and in Germany the figure was 5 times In countries with a smaller population, as already mentioned, the variations were greater. Thus in Scotland and Denmark the maximum rate was 17 times the minimum, and in Switzerland 23 times as great, exceptions to the general rule did occur, and in Belgium, Spain, and the Netherlands there were only small variations recorded

Examinations of the mortality curves for the whole decade showed a tendency for a phase of low mortality to succeed immediately one of high mortality. For example, in Germany in 1923 the mortality rate was 13 4 and 2 6 in 1924, in England in 1920, 19 2, in 1921, 5 9, in Sweden 9 1 in 1924 and 1 1 in 1925; and so forth

Measles in tropical lands generally presents similar features to those found in more temperate climates. The disease may assume serious proportions among workers on tea estates and other plantations where isolation is virtually impossible (Kingsbury, 1928, Manson, 1935). Kingsbury has pointed out that children may suffer from bronchitis probably due to the passage of ankylostomes and ascarides through the lungs.

Estimates of the Number of Susceptibles

Various mathematical investigations have shown that it is possible to determine the precise number of susceptibles in any one community (Hamer, 1906, Brownlee, 1908–9, Stocks and Karn, 1928, Hedrich, 1930, 1933). In estimating the number of susceptibles it must be taken into account that a number of children become temporarily immune due to latent infection. This fact has been largely established by Stocks, who has shown that about 4 to 5 times as many children as suffer from actual attacks acquire immunization sufficient to protect them for one winter (Stocks and Karn, 1928, Stocks, 1930, 1933).

Periodicity of Measles Epidemics

It is well known that measles epidemics in any one area tend to recur regularly. The interval between epidemics, or as it is called the "period," is usually approximately 2 years. This question of periodicity has been studied by a number of authors (e g, Hamer, 1906, MacNalty and Wheaton, 1918, Brownlee, 1916–18, 1918–19, 1919, Picken, 1921, Soper, 1929, Petersen, 1940) Greenwood (1935) gave an excellent review of the subject. Butler (1946, 1947 *b*) describes a 2-year periodicity in Great Britain of recent years There is a small increase in incidence from January to July, with a partial decrease in the autumn The main incidence is in November to March There is only a short interval between the end of one cycle and the beginning of the next The partial evacuation of children from London at the beginning of the second world war led to a postponement of the 1940 epidemic (Martin, 1942, Stocks, 1942, Swyer, 1942). The presence of periodicity is undoubted, but to explain it is more difficult

1. The older view, enunciated by Hamer (1906), conceived the progress of a measles epidemic as a relatively simple affair. At the start each case gives rise to several more cases, and the curve ascends steeply Then a critical period is reached and eventually the epidemic declines as each case does not invariably give rise to another. This explanation was further elaborated by Soper (1929) to include the effect of seasonal variation

2. This theory supposes that periodicity is largely due to an alternating increase and decrease in susceptibles Observations on measles in London from 1900 to 1918

recorded in patients aged 57 (Hall, 1930), 71 (Frewin, 1931), and 76 (Graham, 1930).

Seasonal incidence. In his work on periodicity in measles (*vide infra*), Brownlee discussed the question of seasonal periodicity. Thus he found there were usually 2 maxima of incidence, in winter and in spring In London, he found the highest incidence in December and in April or May. In Edinburgh, Bristol, Birmingham, Sheffield, and Manchester the spring outbreak was the major one. In Newcastle, Liverpool, Glasgow, and Salford the 2 outbreaks were of equal importance. London suffered from an annual spring outbreak and Brownlee suggested that this was due to the prevalence of an epidemic with a strictly annual period Hindman and Harmon (1934) have also investigated the seasonal incidence of measles in America

In Europe, from 1926 to 1931, no less than 92 per cent. of the annual maximal periods of morbidity occurred from December to May (*League of Nations Epidemiological Reports*, 1932). Although in Europe the maximal morbidity and mortality occurred in the winter and spring, in Spain, Portugal, and Egypt it was in the hot weather. In contrast the maxima occurred in the cold weather in Algeria, Turkey, Palestine, and Iraq.

Influence of Degree of Exposure

Measles is, of course, a highly infective disease, but it stands to reason that the more intimate the degree of exposure the more certain is the infection to develop (see, e.g, Aycock, 1934, Karelitz and Schick, 1935). Discussing the work of Top (1937) and personal observations, Karelitz and Karelitz (1938) concluded that the incidence of measles rises with the intensity and duration of exposure to the source of infection, for periods of exposure up to about 8 days. Thereafter, increased exposure does not appear to raise the incidence.

There is no doubt, from these recent and many other studies, that the most intimate type of exposure occurs in the home, and not in schools, wards, vehicles, or at parties (see in particular, Karelitz and Karelitz, 1938). In conformity with this view, it is generally easier to secure protection with antiserum *in the hygienic* conditions of a hospital ward than it is in the private house (Karelitz and Schick, 1935) In further support of the importance of home exposure, with regard to overcrowding and housing conditions, Halliday (1928) found that the slum child tended to be exposed to infection earlier than well-to-do children, while Picken (1921) showed that the incidence of measles in one-apartment houses was about 6 times that in larger houses (see also section on Mortality) Stillerman and Thalheimer (1944) found that the secondary attack rate in 200 intimately exposed susceptible family contacts aged 1 month to 14 years was 75 per cent. The attack rate was lowest for children in early infancy, highest for those aged 1–7 years (80–90 per cent), and only 15 per cent for those 10–14

Geographical Distribution of Measles

Measles has been endemic in most parts of the world for many years. In certain isolated communities, however, infection has only occurred at long intervals, usually due to the arrival of a case from an infected ship (*vide infra*). The bulk of the following information is summarized from the special report of the League of Nations on the World Distribution of Measles from 1919 to 1931 (*League of Nations Epidemiological Reports*, 1932)

Measles differs from many other contagious diseases in that it does not evolve synchronously in neighboring countries Thus one cannot say that such-and-such a year was a "measles year" throughout the world, each country functions as a separate unit In any given country the morbidity and mortality curves may be very erratic, the variations being greater in the smaller countries This is because the smaller countries comprise epidemiological units in themselves, roughly comparable to a single city of a larger country. In the small country there will be

to 25. There were 11,000 cases in Tonga following the arrival of a ship with a case on board (Carrick, 1939).

Hawaii was visited by a very severe outbreak in 1936–7 (see *Public Health Report*, 1937) The mortality was extremely high: 102 per 100,000 The population was thought to be particularly susceptible as measles had been infrequent for the previous 5 years

Faroes. Measles was prevalent in the Faroes in 1781, but one of the most classical of all these types of outbreak occurred in 1846, and was described by Panum (1847, 1851).[1] Within 6 months 6,000 out of the 7,782 inhabitants had become infected Those old persons who had had measles in 1781 were immune, whereas contemporaries who had escaped at that time now contracted it The case mortality was low, only 1.7 per cent., although the morbidity figure was so high. Staermose and Kofoed (1938) described an outbreak in adults following a meeting to obtain whale flesh.

Other outbreaks. Numerous other outbreaks of a similar nature have been recorded (see Hirsch, 1883) in India, China, Japan, Egypt, Abyssinia, Tunis, West Coast of Africa, Australia, New Zealand, and other places. A particularly severe outbreak involved the Hudson Bay Indians, and another the Amazon natives in 1749

The Control of Measles

Measles attacks the great majority of persons, and the bulk of the mortality occurs in children in the first few years of life. What can be done to deal with the situation? The following measures have been suggested by various authorities (e g, Brownlee, 1920, Halliday, 1928, Ruhland and Silverman, 1928; Stocks, 1931, Gunn, 1942)

1. Special attention should be paid to children under 3 years of age. During a measles epidemic they should not attend any meeting places or have undue intercourse with other children Contacts may be sent away to houses in the country or less crowded surroundings where there is less chance of disseminating the infection.

2. Quarantine need not be strictly enforced for the first week after exposure, but should continue thereafter for 10 to 14 days.

3. Weakly children exposed to infection should be injected with convalescent serum early in the incubation period In the case of other, more robust, children, sero-attenuation should be aimed at in every case (*vide infra*).

4 In all cases particular attention should be paid to early diagnosis Parents, school teachers, and all youth workers should be well instructed in the prodromal manifestations of measles Children developing catarrhal symptoms must be isolated at once

5. Extra home-nursing as well as medical facilities should be freely available. There is an increasing tendency to urge hospitalization, especially of the poorer classes (see Brincker, 1936)

6. It has been suggested that children should be actively immunized by inoculation of virus on the nasal mucosa, a "covering" dose of convalescent serum being given later (*vide infra*)

By widespread adoption of such methods it is probable that measles could be largely prevented, indeed Stocks (1931) has stated that theoretically measles could be completely eradicated To the adoption of such regulations in Syracuse (U S A.) Ruhland and Silverman (1928) attributed a fall in the case fatality rate for children under 3 years from 5 1 per cent to 1 6 per cent. Certain methods will be discussed further

[1] Appreciations of Panum's important observations as well as English translations of extracts from his papers have appeared (Little, 1931, Gafafer, 1935–6).

may be quoted to illustrate this theory. Thus, measles did not arise in a community until the number of susceptibles rose to 25 per cent. Once the epidemic began it did not flare up at once, but rather it gathered speed slowly, waiting perhaps for a suitable combination of factors The epidemic did not cease till the number of susceptibles fell to 20 per cent. (Brincker, 1936). Continuing the cycle, with the passage of time, susceptibles began to increase again, as more children were born, while those not previously attacked remained susceptible. Eventually there arose a high enough percentage of susceptibles and a further epidemic occurred.

It has already been mentioned briefly that a certain number of persons acquire immunity by latent immunization. Although they do not suffer from any obvious manifestations of the disease, they none the less become immune to it. This concept has followed largely from the work of Stocks and Karn (1928), who examined the *measles statistics in the London borough of* St. Pancras from 1916 to 1918 (see also Stocks, 1930). They followed the measles histories of children in homes in which there had been cases, and contrasted them with children from noninfected homes. They found that there was a definitely lower incidence of measles in those children known to have been exposed to infection. The other children also appeared to have acquired some immunity, but this did not last so long, probably for about 18 months. Stock [illegible]
don boroughs of [illegible]

There is thus [illegible]
tions in immunity. During an epidemic there is a great increase in immunes, composed partly of recovered cases and partly of those becoming latently immunized. After the epidemic the latent immunity passes off and newborn children help to swell the increasing number of susceptibles When the number is high enough a further outbreak arises and the cycle proceeds as before

3 Brownlee attributed periodicity to the biological activity of the infecting organism—alternate phases of quiescence and activity being postulated

Conclusions.

The most characteristic feature of a measles epidemic is its periodicity, but it must be confessed that the mechanism responsible for this is somewhat obscure. Brownlee attributed the phenomenon mainly to a factor inherent in the organism Stocks and Karn, on the other hand, think that the phenomenon of fluctuations in immunity, mainly dependent on latent immunization, is the most likely explanation. Greenwood (1935) in his discussion of this subject inclines to the opinion that immunity mechanisms play the predominant rôle.

Measles Epidemics in Virgin Soil

Measles is endemic in most of the congested parts of the world, but is often absent in isolated communities Certain of these communities, especially island ones, have suffered from time to time in a characteristic fashion Measles has usually been introduced by an infected person on board ship In these outbreaks all persons have been susceptible, irrespective of age, the attack rate has been very high and there has often been a high percentage of fatalities Certain of the best known of such visitations will now be described, but those who desire further information should consult the comprehensive article of Hirsch (1883)

Pacific Islands. A severe outbreak of measles occurred in Fiji in 1875, when approximately 25 per cent of the natives died (Corney, 1883–4) In 1911 the island of Routumá was visited by measles following the call of a ship with a case on board (MacDonald, 1912, Corney, 1912–13) There had been no previous outbreak in this island for at least a generation The death rate figure reached 246 5 per 1,000, the majority of deaths occurred in young children and in adults aged 20

ultraviolet light. Some success seems to have attended this work (Wells, Wells, and Wilder, 1942, Wells, 1945).

Education of parents.

This necessary duty has been repeatedly stressed Health authorities should instruct parents that measles in children under 3 is a very dangerous disease. If the attack can be postponed till a later age the child is more likely to survive. Parents of children under 5 should keep them at home during measles epidemics

Nursing and hospitalization.

Probably home treatment is perfectly satisfactory provided a district or other nurse can attend regularly. If this is not possible, or the house very unsuitable, hospitalization should be carried out As has been said, there is an increasing tendency to effect hospitalization, many feel that in this way complications can be recognized more readily and treated more efficiently. However, recent observations on the frequency of cross infection in open measles wards (see above) point to the necessity for discrimination in urging hospitalization Cruickshank (1943), for instance, suggests that children should be sent only if home conditions are poor. Wright (1945) makes the following recommendations for nursing measles cases in hospital, to reduce the risk of cross infection (1) There should be 12 feet between beds (2) Infants under 1 should have a priority on isolation accommodation (3) Patients with suspected streptococcal infection should be isolated (4) Patients must not be moved directly from one open ward to another. (5) Dust-suppressive measures should be taken, including the use of oil (6) Individual equipment must be used for nasal toilets, and nurses must wash their hands after each treatment. (7) Whenever possible, fomites should be sterilized between each usage. (8) Barrier nursing should be used for any patient developing intercurrent respiratory, gastro-intestinal, or skin infection (9) Nurses should wear masks

It seems probable that sulfadiazine administered as a routine to all children in the ward may reduce the incidence of cross infection (Begg, Smellie, and Wright, 1947).

Measles Outbreaks in Hospitals and Children's Institutions

To obviate quarantine Steinholz (1933) has recommended the following scheme.

1. The primary case is transferred to a fever hospital.
2. Each susceptible in the ward is given 40 c c. of parental whole blood
3. Any new cases, certified to have had measles, may be admitted
4. Other entrants receive 40 c c. of blood
5. All cases that have had measles may be discharged when the time arrives
6. Cases that have been injected with whole blood may not be discharged until at least 14 days have elapsed By such means Steinholz claims to be able to keep a ward open and in working order

Crosbie (1938) has also reported on the successful application of a similar method He removes the case and immunizes all contacts with adult serum or globulin (placental) The ward need not be closed if all entrants have had measles The Medical Research Council in Great Britain (1944) recommends 2 alternatives (*a*) to protect all susceptibles with convalescent serum and to continue to admit, or (*b*) to protect all children under 3, and older debilitated children, and to secure attenuation in older robust children, the ward being quarantined for 21 days

Notification.

It is questionable how far notification is of value in restricting the spread of infection, but some believe that it has this effect Thus Boyd (1928), discussing the value of reporting in Pretoria, attributes a fall in death rate from 1.38 per 1,000 in 1907–12 to 0 26 in 1922–7 as due partly to the increased control of cases and contacts rendered possible by notification As in other infections, probably many cases are never reported. For example, in the United States, Sydenstricker and Hedric (1929) found that only 25 8 per cent of the entire incidence was reported

Measles in schools.

The question of measles in schools is one of great importance, for it is here, indubitably, that the majority of children contract their infection

Boarding schools A special committee of the Medical Research Council (*Report*, 1938) found that measles is more likely to spread than any other infective fever, and they recorded an attack rate on susceptibles of up to 88 per cent.

Day schools. During a measles epidemic practically every day school will be infected, and become the main disseminator of infection.

Nursery schools. It has been shown that children attending day nurseries are much more likely to develop measles than children who stay at home. They tend further to develop it at an earlier stage and more especially in the winter—both serious points as regards mortality (McLaughlin, 1947)

Exclusion from school The official regulations of Great Britain, issued jointly by the Ministry of Health and the Board of Education (*Memorandum*, 1942), can be summarized as follows

1 Children attacked by measles should be kept from school for 2 weeks from the first appearance of the rash.

2. As regards contacts, infants who have not had the disease should be excluded for 14 days from the date of the appearance of the rash in the last case in the house Other contacts can attend Any contact with a cough, cold, chill, or red eyes should at once be excluded

Forbes of Brighton consistently criticized the value of exclusion of home contacts (1930, 1933, 1936, 1939) He states that home contacts attending infected schools should not be excluded, although the contacts attending uninfected schools should be Exclusion during the long incubation period is useless, while exclusion toward the end of this period allows the child to run about in and near his home infecting infants, as prodromal catarrh is seldom regarded by the parents as adequate grounds for keeping the child indoors Whereas, Forbes states, if the child attends school his prodromal symptoms will be recognized at once and the child sent home out of harm's way

Forbes, however, urges the exclusion of "under fives" from infected schools, or from noninfected schools if weakly, or living in unhealthy surroundings (see, e.g, 1933)

In Brighton, since 1923, home contacts attending infected schools have not been excluded Home contacts attending uninfected schools are excluded, however These procedures result in a minimum loss of school attendance

School closure School closure usually results in a slowing-down of the epidemic but it flares up again on reopening It may, however, be of use in the prevention of respiratory fatalities during very inclement weather (Forbes, 1930, 1933, 1936) The official regulations state that school closure is generally useless, but in country districts where the children have to come some distance it may prove an effective measure Crèches should be closed during a measles epidemic (Forbes, 1930)

Ultraviolet irradiation On the assumption that measles is largely spread by droplet nuclei, experiments have been carried out by irradiating classrooms with

rash on intradermal injection of susceptibles, and can be neutralized by measles convalescent serum (Ferry and Fisher, 1926). Measles convalescent serum agglutinates the organism (Ferry and Fisher, 1926, Ferry, 1929). Antitoxin produced in animals was said to give protection against measles (Ferry, 1929, Ferry *et al*, 1928)

[illegible]

staphylococci, diphtheroids, and influenza bacilli are all mentioned as having been found in measles cases (see Thomson and Thomson, 1931).

Nonconfirmatory work. The impression will have been gained that there is, apparently, no one specific measles bacterium, for a variety of different cocci and other organisms has been claimed as etiological by their respective discoverers The diversity of types of "measles cocci" was stressed by Park *et al* (1927) who isolated a great variety from cases of measles Ferry and Noble (1929) also noted the wide range of variation among the various "measles cocci." Park *et al.* were unable to differentiate between immunes and nonimmunes by intracutaneous injection of toxins prepared from "measles cocci" (see also Smith and Fraser, 1928–9) Bradford (1929) also found the skin test valueless as a means of distinguishing between immunes and susceptibles, using Tunnicliff's coccus and *S. morbilli*. Various workers have failed to isolate green-producing cocci from the blood (see, e g., Long and Cornwell, 1927) Other workers have isolated "measles cocci" from the pharynx of measles cases but no more commonly than from healthy persons Thus Smith (1928–9) found no evidence that these cocci were other than part of the normal flora of the upper respiratory tract, and the majority of bacteriologists agrees with this view It is evident, therefore, that there is no substantial basis for believing that measles is caused by cultivable bacteria. We shall now describe the properties of the virus believed to be the true causal agent.

THE VIRUS OF MEASLES

Measles was probably first shown to be an infective disease by Mayr (1852), and later by Hektoen (1905), who employed human inoculation experiments. Josias (1898), one of the first to attempt animal transmission, inoculated monkeys with measles secretions and obtained a slight rise of temperature and a rash However, little advance was made till 1911 when a number of investigators reported the susceptibility of the monkey In the same year the etiological agent was shown to pass a Berkefeld filter by Goldberger and Anderson (1911 *b*), thus definitely establishing measles as a virus disease.

Human Inoculation Experiments

The work of Home (1759) is always quoted in this respect He inoculated some 15 children with measles blood by scarification, the majority developed a rash and pyrexia, but within an incubation period of 10 days Rigid precautions to exclude outside infection do not seem to have been made Home's work was pioneer and therefore of great value, but as his experiments were scarcely sufficiently controlled it is not possible to accept that he actually transmitted the infection Mayr (1852) infected susceptibles by inoculating them intranasally with nasal secretion from measles cases He also produced a mild attack by scarifying the skin with swabbings from a measles lesion. A number of inoculation experiments of a doubtful nature was carried out between the time of Home and that of Hektoen (1905) These have been reviewed by Hektoen and also by Kato (1928)

Hektoen (1905) withdrew blood from a case of measles on the fourth day and inoculated 4 c c. into ascites broth, after 24 hours the mixture was injected subcutaneously into a human volunteer, who had been quarantined This patient developed a transient pyrexia after 14 days From another case Hektoen withdrew

CHAPTER XXI

THE VIRUS OF MEASLES

RÔLE OF CULTIVABLE BACTERIA

VARIOUS bacteria have been claimed as the cause of measles, but it is now generally believed that measles is a virus disease, and that these organisms are accidental contaminants or perhaps secondary invaders. Those interested in the question of the cultivable "measles bacteria" should consult the exhaustive monographs published by Thomson (1924,[1] 1926, Thomson and Thomson, 1931). These organisms will now be discussed separately.

Tunnicliff's coccus. Perhaps the most extensive work on "measles cocci" has been carried out by Tunnicliff and coworkers and their main findings may be summarized as follows·

(*a*) A diplococcus, *Diplococcus morbillorum*, occurs in the blood of measles cases, during the preeruptive and eruptive stages, as well as in the throat, eyes, and nose. This organism grows, at first anaerobically, in semicoagulated horse serum and whole blood ascitic dextrose agar shakes; later, aerobic growth occurs. The organism can be subcultured on blood agar and produces green or α-hemolysis A filtrable exotoxin is produced (Tunnicliff, 1917, 1918).

(*b*) Measles diplococci are immunologically distinct from nearly all similar cocci, but lose their specificity by growing in immune horse serum, or at 40° C. (Tunnicliff, 1927, 1933).

(*c*) The organism is filtrable through a Berkefeld N filter when occurring in exudates, but not in cultures (Duval and Luzenberg, 1932–3).

(*d*) Convalescent measles serum and diplococci fix complement (Tunnicliff and Brown, 1918). Convalescent serum agglutinates diplococci (Tunnicliff, 1919) Placental extract and convalescent serum have a high opsonic effect on the diplococci (Tunnicliff, 1936)

(*e*) Rabbits injected with diplococci show a rise of temperature, Koplik's spots, and an eruption.

(*f*) Injected rabbits show the development of specific serum opsonins and agglutinins (Tunnicliff and Brown, 1918)

(*g*) A goat serum with antitoxic and antibacterial powers was produced by injection of diplococci and filtrates This was said to have a prophylactic effect in children exposed to infection (Tunnicliff and Hoyne, 1926 *a*, *b*).

(*h*) This goat serum protected rabbits against injections of infective measles material (Tunnicliff and Hoyne, 1926 *b*)

(*i*) Diplococcal cultures and filtrates produce a skin rash in susceptibles, but not in persons who have had measles This toxin is neutralized by convalescent measles serum and goat serum (Tunnicliff, 1925, Tunnicliff and Taylor, 1926)

Caronia's coccus Caronia isolated a small gram-negative diplococcus from the blood and secretions of measles cases, during the rash and prodromally (see, e g, 1923). This organism grew anaerobically in Tarozzi-Noguchi's medium Convalescent serum showed agglutination and opsonization of these cocci The injection of rabbits with cocci produced a measles-like infection Meyer (1925–6), however, isolated similar cocci from control material

Ferry's coccus The name of *Streptococcus morbilli* has been given to a streptococcus isolated from the blood of measles cases by Ferry and Fisher (1926) The organism is gram-positive and grows aerobically It produces a toxin which gives a

[1] References are appended at the conclusion of Ch XXII, p 235 et seq

(*a*) A rise of temperature may occur after 8 to 11 days, the temperature may remain raised, be remittent, or soon fall.

(*b*) Catarrh affecting the nose and eyes develops in about 50 per cent.

(*c*) About 3 to 4 days after the fever a discrete roseolar papular rash develops, especially on the face and chin and spreading to the neck, chest, abdomen, upper arms, and thighs (Blake and Trask, 1921 *a*, *b*). Brown scaling occurs later

(*d*) Koplik's spots may be seen as discrete red spots on the inside of the lips (Lucas and Prizer, 1912, Kawamura, 1922, Blake and Trask, 1921 *a*, *b*).

(*e*) In the preeruptive stage a leukopenia may develop, although shortly after inoculation there is a leukocytosis (Hektoen and Eggers, 1911, Lucas and Prizer, 1912, Tunnicliff, 1912, Blake and Trask, 1921 *a*, *b*, Torres and Teixeria, 1932 *a*) In the leukopenic stage Tunnicliff (1912) found that there was a decided decrease in the phagocytic activity of the leukocytes

(*f*) Hurst and Cooke (1941) could not pass the infection in series for more than 4–6 transfers

The distribution of the virus in infected monkeys The virus must be present in the catarrhal secretions as infection has been spread by contact (Goldberger and Anderson, 1911 *a*). The virus is present in the buccal mucosa of infected monkeys killed 2 to 6 days from the onset (Blake and Trask, 1921 *a*). The virus is found in the blood 24 hours before the appearance of Koplik's spots and persists for 36 hours after the appearance of the rash (Lucas and Prizer, 1912) Confirming these findings, Blake and Trask (1921 *a*) found monkey blood infective for the first 5 days of the illness Plotz (1938 *b*) found that virus might persist in the blood of inoculated animals in the absence of symptoms

Pathology The histological features of the skin rash have been studied by Blake and Trask (1921 *b*) as well as by Lipschutz (1928). The corium shows multiplication of the endothelial leukocytes with extravascular emigration The cyto-

epidermis shows

with the eventual

rosis of epithelial

(1928) has found

(*vide supra*)

The mucosa of the lips presents a similar picture with activity of the endothelial leukocytes in the deeper layers, this reaction is also evident beneath the stratified epithelium where the cells collect in small foci. Vacuolation and necrosis of the epithelial cells occur also. It will be noted that the features described in the skin and labial mucosa are very similar to those found in human lesions Giant cells have been described in lymph nodes (Gordon and Knighton, 1941)

Rabbits.

A number of authors has reported on the susceptibility of rabbits (Nevin and Bittman, 1921, Harde, 1921, Duval and D'Aunoy, 1922 *b*, *c*, Tunnicliff and Moody, 1922, Grund, 1922, Caronia, 1923, Scott and Simon, 1924 *a*, *b*, 1925, Hibbard and Duval, 1925–6, Belikoff, Dwijkoff, and Truschina, 1929, Baar and Benedict, 1931, Taniguchi *et al*, 1935)

Rabbits can be injected intravenously or intratracheally, and various reactions may develop following an incubation period of 2 to 5 days

(*a*) Pyrexia

(*b*) Many have recorded leukopenia, although carefully controlled work by Purdy (1925) did not show any such reaction

(*c*) Coryza, conjunctivitis, and upper respiratory tract inflammation

(*d*) Koplik's spots

(*e*) A *maculopapular rash develops on the face, chest, neck*, and abdomen

(*f*) Orchitis may rarely follow an intravenous injection (Taniguchi *et al*, 1935) Post mortem, nephritis may be found

blood 30 hours after the appearance of the rash. After being placed in broth, the blood was injected subcutaneously into a patient. On the eleventh day pyrexia, cough, conjunctivitis, and tonsillitis developed, while on the fourteenth there was a rash. There seems to be little doubt that Hektoen was one of the first to demonstrate the infectivity of measles in a convincing manner. It should be added, however, that Sellards (*1919 a, b*) failed on many occasions to transmit the infection by injections of human blood.

Adducing further evidence on the infectivity of blood, Bauguess (*1924*) reported that measles had been conveyed in the course of a blood transfusion from a donor in the prodromal stage of measles. Degkwitz (*1927*) reported that measles could be reproduced in man by inoculations of Berkefeld-filtered blood, and filtrates of nasal secretions. Taniguchi's virus, maintained by rabbit testicular passage, produced localized papules and vesicles on intradermal injection and generalization sometimes occurred (Taniguchi *et al*, *1935*). Later workers have demonstrated the infectivity of measles blood for children (Shaffer *et al.*, *1941*, Rake, *1943*).

Children have been infected with virus cultivated on the chorio-allantois, following nasal instillation, inhalation, intradermal or subcutaneous injection. The intradermal and inhalation methods of introduction of virus secure infection in the majority, but nasal instillation is less certain. The symptoms are usually mild, and the infection is characterized by Koplik's spots, rash, fever, conjunctivitis, coryza, and leukopenia (Shaffer *et al*, *1941*; Rake, *1943*, Stokes *et al.*, *1943*).

Animal Experiments

Monkeys.

Numerous investigators have shown the monkey to be susceptible to experimental measles (Nicolle and Conseil, *1911*, Anderson and Goldberger, *1911 a, b*, Goldberger and Anderson, *1911 a, b*, Hektoen and Eggers, *1911*; Lucas and Prizer, *1912*, Tunnicliff, *1912*, Blake and Trask, *1921 a, b, c*, Nevin and Bittman, *1921*, Tunnicliff and Moody, *1922*, Purdy, *1925*; Hibbard and Duval, *1925–6*, Degkwitz, *1927*, *1927–8*, Lipschutz, *1928*, Torres and Teixeria, *1932 a*; Taniguchi *et al*, *1935*, Plotz, *1938 a, b*, Rake and Shaffer, *1939*, *1940*, Shaffer *et al.*, *1941*; Gordon and Knighton, *1941*, Hurst and Cooke, *1941*, Shaffer, Rake, and Hodes, *1942*, Konowa *et al*, *1945*).

The following species of monkey have been found susceptible *Macacus sinicus* (the bonnet monkey), used by Nicolle and Conseil (*1911*), cynomologus and rhesus monkeys (Goldberger and Anderson, *1911 a*), and *Macacus fuscatus* (Kawamura, *1922*) Hurst and Cooke (*1941*) found the following susceptible. *M. mulatta*, *M radialus*, and *Cebus fatuellus* The following were negative· *M. irus*, *M. maurus*, and *Cynopithecus niger*. The inoculum in these experiments has often been human blood, mixed catarrhal secretions have also been used, as well as preparations of the exanthem Monkeys are susceptible to virus grown in the egg or tissue culture and develop symptoms similar to those found by workers using human material (Rake and Shaffer, *1939*, *1940*, Rake, Shaffer, and Jones, *1941*, Shaffer *et al.*, *1941*, Rake, *1943*)

Routes of inoculation. Monkeys can be infected by a variety of routes combined intracerebrally and intraperitoneally (Anderson and Goldberger, *1911 a*), by contact between a healthy monkey and one in the catarrhal stage (Goldberger and Anderson, *1911 a*), subcutaneously (Goldberger and Anderson, *1911 a*, Kawamura, *1922*), by spraying and swabbing the mouth and throat with catarrhal secretions (Goldberger and Anderson, *1911 a*), intravenously (Blake and Trask, *1921 b*), intratracheally (Blake and Trask, *1921 a, b, c*), intranasally Hurst and Cooke (*1941*) found splenectomized monkeys were more susceptible.

Course Following injection there is an incubation period of 6 to 11 days after which a variety of symptoms may develop (see in particular, Blake and Trask, *1921 a, b*)

on human injection (Degkwitz, 1927). Ueda (1937) also reported cultivation of the virus by the hanging-drop method. Plotz (1938 *a*) claims to have cultivated the virus from human blood by growth in a chick embryo, Tyrode, serum medium, tenth passage material provoked a typical reaction on inoculation in a monkey. Rake, Shaffer, and Jones (1941) also propagated virus in tissue cultures.

Pocks were produced on the chorio-allantois after inoculation of the egg with material from a measles skin lesion (Torres and Teixeria, 1935). Microscopically, the pocks consisted of nodular ectodermal proliferations, polymorphic infiltrations were found in the mesoderm.

The virus has been grown on the chorio-allantois from blood removed in the preeruptive stage (Wenckebach and Kunert, 1937). Degkwitz and Mayer (1937) have also reported growth on the chorio-allantois. Taniguchi's virus also grows on the chorio-allantois (Taniguchi *et al*, 1935).

These earlier observations have been abundantly confirmed of recent years and chorio-allantoic virus has been used in human immunization experiments (Heinzmann, 1939, Rake and Shaffer, 1939, 1940, Mayer, 1941, Rake, Shaffer, and Jones, 1941, Maris *et al*, 1943, Rake, 1943; Stokes *et al*, 1943).

Muller (1942), however, obtained negative results. Hurst and Cooke (1941) could not infect by the amniotic route.

Resistance to Physical and Chemical Agents

The virus is destroyed at 55° C. in a quarter of an hour (Goldberger and Anderson, 1911 *b*). It can be preserved at 0° C. for several days, or at −35° C. for 4 weeks (Rake and Shaffer, 1940). Tissue dried *in vacuo* from the frozen state retained virulence for several months (Hurst and Cooke, 1941).

Degkwitz (1927) found that the virus survived for some weeks if blood was drawn off in the early eruptive stage and diluted 1 7 to 1.10 with saline, and kept at 0° C

The virus resists 50 per cent. glycerol for 3 months (Taniguchi *et al*, 1935).

The virus resists 10 per cent. ether at room temperature for 30–40 minutes (Rake and Shaffer, 1940; Rake, Shaffer, and Jones, 1941).

Relationship to Other Viruses

It is generally agreed that the virus of measles is quite distinct from other virus agents. Thus Taniguchi showed that his virus could be absolutely separated (by viricidal tests) from vaccinia, varicella, herpes, or virus III (Taniguchi *et al*, 1935).

(g) Harde (1921) reported that if the blood of measles cases was injected intravenously and the skin of the rabbit shaved, an erythema developed 48 hours later and lasted for 24 to 48 hours.

Taniguchi *et al.* (1935) reported that their virus could be transmitted by the cornea, anterior chamber, and rarely, by intracerebral injection; following intracutaneous injection a local eruption developed. After intratesticular injection an acute orchitis developed (see also Ueda, 1937).

Other workers have failed to infect rabbits (Gordon and Knighton, 1941, Hurst and Cooke, 1941).

Guinea-pigs.

These animals have also been found susceptible (Duval and D'Aunoy, 1922 *a, c*, Tunnicliff and Moody, 1922; Hibbard and Duval, 1925–6; Kawakubo, 1932, Taniguchi *et al.*, 1935; Ueda, 1937; Konov, 1943). When injected intracardially or intratracheally the following symptoms may develop after 9 to 12 days. rise in temperature, leukopenia; at postmortem an intense hemorrhagic nephritis may be found. Animals can also be infected intratesticularly when fever and leukopenia develop with local swelling (Kawakubo, 1932, Taniguchi *et al*, 1935, Ueda, 1937, Marotta, 1939 *a*), microscopically there is atrophy of the seminiferous tubules with an interstitial infiltration of histiocytes and mononuclears In addition to orchitis an interstitial pneumonia is found, and there may be cellular infiltrations in the liver, kidneys, and heart Taniguchi *et al*, (1935) further reported that guinea-pigs could be infected corneally and intracutaneously. Gordon and Knighton (1941) were unable to infect these animals

Other animals.

Mice can be infected corneally and intracerebrally, and fowls and pigeons intracutaneously (Taniguchi *et al*, 1935). Gavrilov (1939) also claimed to have infected mice. Rats could not be infected (Gordon and Knighton, 1941)

Morphology and Filtrability

Elementary bodies (0 25 μ diameter) were found in preparations made from the corneal epithelium of the rabbit (Taniguchi *et al*, 1935) Elementary bodies (slightly larger than Paschen bodies) were found by Coles (1937) in the blood, nasal, throat, and lacrimal secretions

Various types of inclusion body have been described in the skin lesions (*vide supra*), some of these are probably purely degenerative such as the mulberry, ring, and crescentic forms Structures which may represent the etiological agent are those described by Lipschutz (1928, 1929) They are small intracytoplasmic basophilic granules found in the epidermal cells Further study is required, however, before the precise nature of these bodies can be ascertained Broadhurst *et al* (1937, 1938) have recently reported small granular inclusions in human blood monocytes, Koplik's spots, and the nasal mucosa These inclusions develop also if blood cells are grown in tissue culture The cell may break down, liberating small granular elementary bodies Growths of fibroblasts can be infected with measles virus, inclusions developing in the newly formed cells. The bodies are best stained by nigrosin.

The virus is filtrable through the following filters Berkefeld N (Goldberger and Anderson, 1911 *b*; Degkwitz, 1927, 1927–8, Blake and Trask, 1921 *a*, Taniguchi *et al*, 1935), Seitz EK (Wenckebach and Kunert, 1937, Rake and Shaffer, 1939 1940)

Cultivation

It has been reported that the virus can be grown in plasma (diluted with saline 1.6 to 1 7), and that sterile filtrates of such cultures provoke a measles-like reaction

Papp, 1936*a*, Phillips, 1938). The neutralizing power develops by the seventh day of the disease, but is much more potent by the thirteenth (Papp, 1936*b*). Debré suggested that the reaction might serve as an approximate guide to the potency of convalescent serum Papp (1936*a*), however, found that serum might be quite effective in sero-attenuation of measles but fail to give a positive Debré reaction. The reaction is of no value during the period of the eruption, as blanching does not occur (Kingsbury, 1928).

Virus neutralizing antibody can also be demonstrated by its power of inhibiting the development of lesions on the chorio-allantois (Mayer, 1941).

Orlov (1945) has reported that immune serum fixes complement with nasopharyngeal washings or a suspension of lungs of mice inoculated nasally.

Seroprophylaxis of Measles

A variety of biological agents may be employed in the prevention of measles, and it is convenient to use the term "seroprophylaxis" for this technique although the substances do not all, strictly speaking, consist of serum

1. Animal serum.

Certain sera prepared from animals by injection of cocci and other bacterial products have been used in prophylaxis The best known of these are Tunnicliff's measles antitoxin (goat or horse), Ferry and Fisher's measles antitoxin (horse), and Degkwitz's immune serum (sheep)

Tunnicliff's sera were reported on favorably by Tunnicliff and Hoyne (1926*a*, *b*), children exposed to infection did not contract the disease after prophylactic injection of these anticoccal goat and horse sera Halpern (1928) and Peterman (1930) also reported favorably Gunn (1928) found that only about 40 per cent. of contacts became protected after injection of Tunnicliff's serum as against 95 per cent. after convalescent serum Barenberg, Lewis, and Messer (1930) found the serum useless.

Ferry and Fisher's antitoxin was said to protect susceptibles (Ferry *et al.*, 1928, Ferry, 1929) Gunn (1928), however, found that no persons were protected after its injection

Another of these agents was Degkwitz's serum, which was supposed to have been prepared by injection of sheep with various measles exudates Ape serum was also used in some cases The serum was reported on favorably by Degkwitz (1926*a*, *b*, 1927–8), but others found it of little or no use (Zoepffel, 1927, Gunn, 1928, Leiner, 1929, Silverman, 1929, and see McCartney, 1927).

2. Human serum or plasma: convalescent and adult.

It was shown by Nicolle and Conseil in 1918 that convalescent measles serum had the important property of preventing infection in contacts if injected early in the incubation period Rietschel in 1921 showed that whole blood or adult serum was equally effective Debré and Ravina made the important discovery in 1923 that if serum was injected later in the incubation period a mild abortive attack of measles developed The serum can be either convalescent or adult and may be administered in various ways The term "serum" is usually employed although actually plasma is often used Whole blood may also be tried

Convalescent serum has been used by a large number of workers in many parts of the world, and is probably the most popular (e g, by Nicolle and Conseil, 1918, Kutter, 1921, Maggiore, 1921, Zschau, 1921, Blackfan, Peterson, and Conroy, 1923, Zingher, 1924, Copeman, 1926–7, 1929, Park and Freeman, 1926, Benson and Lawrie, 1927, Miller and Smith, 1927, Johannsen, 1928, Gunn, 1928, 1932*a*, *b*, 1938*a*, *b*, Nabarro and Signy, 1929, 1931*a*, *b*, Warwick, 1929, Barenberg, Lewis, and Messer, 1930, Pierret, 1931–2, Hale, 1934, Elkington, 1936, Hyland and Anderson, 1937*a*, *b*,

CHAPTER XXII

IMMUNITY IN MEASLES

EXPERIMENTAL ASPECTS

MONKEYS RECOVERED from infection following inoculation of human material or egg virus are resistant to a subsequent challenge (Blake and Trask, 1921 *c*, Rake and Shaffer, 1939, Hurst and Cooke, 1941; Rake, Shaffer, and Jones, 1941; Konova *et al*, 1945). Guinea-pigs also become resistant (Duval and D'Aunoy, 1922 *a*, Kawakubo, 1932, Marotta, 1939 *b*) Virus neutralizing antibodies have been detected in the *sera of guinea-pigs (Marotta, 1939 b)*.

IMMUNITY REACTIONS IN MAN

Hereditary Immunity

Butler (1912–13) found that from 0–6 months of age, 10 2 per cent. of contacts contracted the infection, while from *6–12 months* the *figure* rose to 77 per cent suggesting the presence of a degree of hereditary immunity (see also Stillerman, Marks, and Thalhimer, 1944).

Active Immunity Following Infection

After an attack, the acquired immunity is usually lifelong in character and of high degree For example, the Faroe islands were visited by measles in 1846, yet persons recovered from the last epidemic in 1781 were immune, despite a lapse of 65 years (Panum, 1847) Relapses are uncommon and occur within 1 month of the original attack (see Desbouis, 1919, Macciotta, 1925; Rolleston, 1926, and Stenn and Stenn, 1939) Second attacks have likewise only rarely been recorded (see Salzmann, 1920, Macciotta, 1925, Erdheim, 1926 *a*, Woolnough, 1929, Pelner, 1941) Matthews (1932) has recorded 4 attacks in 1 case Fouad (1938) recorded a number of second attacks in Egyptian children, 6 children suffered from 2 attacks in the same year

Stocks has emphasized the fact, on statistical evidence, that for every 1 declared case of measles, some 4 to 5 must acquire immunity through latent immunization (see above) Stillerman, Marks, and Thalhimer (1944) found that the percentage of contacts escaping infection increased steadily from ages 1–7 (10–14 per cent) to *10–15 (85 per cent)*

Following the injection of convalescent serum for sero-attenuation, *vide infra*, immunity is acquired

Active Immunity Following Vaccination

Taniguchi *et al*, (1935) produced localized eruptions by intradermal injection Herrman (see 1929) introduced a method of active immunization, which involved applying infective nasal secretion to the nasal mucosa A covering dose of immune serum was given shortly afterward Good results were claimed Latterly, living egg-cultured virus has been used in children, and is said to give some protection against natural infection (Maris *et al*, 1943, Rake, 1943)

Serum Antibodies

Debré and Ravina (1923) reported that if measles convalescent serum was *injected* intradermally in the prodromal period, no rash developed in that particular area This reaction was described independently by Keller and Moro (1925) Other workers have confirmed these findings (e g, Baar, 1931, Nabarro and Signy, 1931 *a*,

adult whole blood 20 c.c. For children over 3, give double these amounts. For attenuation, give the same doses on or after the 6th day, alternatively half the dose may be given within 5 days. A common practice in calculating the dosage of convalescent serum for children over 3, is to multiply the age by 2.

Serum retains its full potency, on ice, for 6 months, thereafter the titer falls to 60 per cent where it remains for a further 18 months (see Burnet, 1935).

Route of injection. Serum is usually injected subcutaneously or intramuscularly. It has been claimed that conjunctival instillation is effective (Anderson and Gérard, 1930) Blossom (1945) gave the serum intradermally (0.4 c.c.) on successive days, giving a total of 2 c.c.

Results It is generally agreed that in a very high percentage of cases measles can be absolutely prevented. Estimates of the percentage of cases which fail to be protected by serum injection given early in the incubation period vary from 2–5 to 20 per cent (Gunn, 1928, 1932 *a*, *b*, Pierret, 1931–2; Hobson, 1934)

Gunn (1938 *b*) has, however, expressed his disappointment with the results obtained by serum administration in the 1935–6 London epidemic; these results have also been fully described in an official *Report* (1938). A protection rate of 72.4 per cent. was obtained in the case of children inoculated with adult serum for prevention, in the 2 previous epidemics the results were 78.3 and 78.6 per cent, respectively. Convalescent serum gave a protection rate of 72.3 per cent. in contrast to 80.8 and 90.7 per cent previously. With regard to attenuation, the rate for adult serum was 31.5 per cent, compared to 38.5 and 37.4 per cent. previously, and for convalescent serum, 20 per cent. compared to 54.3 per cent. previously.

In earlier reports from various authors it appeared that attenuation is the rule if serum is given at the correct time, and it is probable that technical reasons may explain some reported failures. Thus, serum may have been stored for some period. Further, in any large scheme donors may not always be carefully selected and may yield a serum of low titer Another important factor which affects the degree of efficacy of prophylactics is the degree of intimacy of contact (Karelitz and Karelitz, *vide infra*). It is often difficult to judge accurately the day of exposure. The administration of serum may have the effect of prolonging the incubation period, even up to 4–5 weeks

About 3 to 4 per cent of children may show a general reaction, with slight rise of temperature, anorexia, and some local reaction after serum administration (Pierret, 1931–2).

Hepatitis may follow the inoculation of icterogenic batches (Medical Officers, Ministry of Health, 1943). It is hoped that ultraviolet irradiation may destroy any icterogenic agent present in serum.

Municipal schemes Many corporation public health departments have elaborated schemes for the collection, storage, and supply of suitable sera Adult cases of measles and older children are bled during convalescence, adult donors who contracted measles in youth may also be employed Boy Scouts and members of other youth organizations will usually volunteer for such service if asked The serum is generally prepared in a bacteriological laboratory where it may appropriately be examined for sterility and by the Wassermann test. The serum should be stored in a cool place The supply is usually limited and serum is only issued to local practitioners and hospitals for certain specified cases Such schemes have been described by various writers (see, e g, Copeman, 1926–7, Okell, 1932, Williams, 1936, Lemierre, 1937, Gunn, 1938 *b*, *Report*, 1938, Thalhimer, 1938).

Serum globulin The globulin of immune serum has been extracted and found to contain specific antibody, this extract is as powerful as the original serum and has been used prophylactically (Karelitz, 1933–4, 1938, Thalhimer, 1940). Gunn (1938 *b*) has found that both pseudo- and eu-globulins are effective. In the 1935–6 London epidemic the globulin fractions of adult serum gave a protection rate of

Lemierre, 1937, Hobson, 1938, Top and Badger, 1941; De Haas and Posthuma, 1942; Council on Pharmacy and Chemistry, A. M. A., 1943).

Adult serum may be used. Adult serum has been recommended by various authors (e g, Rietschel, 1921; Zingher, 1924; Siegel and Ermann, 1930, Barenberg, Lewis, and Messer, 1930, Morales and Mandry, 1930; Burn, 1931; Karelitz and Schick, 1932; Hunter, 1933, Brincker, 1936, Papp, 1936 c; Hyland and Anderson, 1937 b, Gunn, 1938 b, Champtaloup, 1939, Lempriere, 1939; Bull, 1940; Barenberg et al., 1942; MacKendrick and Seville, 1946).

Reconstituted plasma as used in transfusion work may be employed. Parental serum has been recommended by Barenberg *et al.* (1939).

Preparation of serum. As regards the time of collection, between 7 and 9 days after defervescence is regarded as optimal, and certainly not later than 12 to 14 days (Nabarro and Signy, 1931 *a*, *b*, Pierret, 1931–2).

The method of collection used by Park and Freeman (1926) involves drawing off the blood and running it into a 500 c.c. bottle containing 2 c c. of 25 per cent sodium citrate and 0.3 gm. of oxyquinolin sulfate. The red cells are allowed to settle by gravity in the refrigerator, or by centrifugation. The plasma is sealed into 3 c c and 6 c c ampules and 30 c.c. bottles. Wassermann and sterility tests are, of course, carried out on each sample A similar method was advocated by Nabarro and Signy (1931 *a*).

The method we have used involves the separation of serum from the patient's clotted blood, filtration of pooled samples is then carried out through a large Seitz filter. The serum is finally filled into ampules and stored until required. Wassermann and sterility tests are, of course, performed.

Another excellent method of preparation is to desiccate the serum *in vacuo* in ampules and then, before use, add sterile distilled water to reconstitute the original bulk.

Method of administration According to the day on which the serum is administered, so one hopes either entirely to prevent any attack developing, or, alternatively, to produce a mild modified illness. Serum administered in the first 5 to 6 days of the incubation period usually protects completely, while between the 6th and 9th days it results in a modified attack The day of appearance of the rash in the primary case is regarded as the 4th day.

After the 9th day the illness is seldom prevented or modified, although it has been claimed that the administration of 40–50 c c. of serum intravenously in the catarrhal stage has a beneficial effect (Kohn, Klein, and Schwarz, 1938, 1941; Thalhimer, 1940, Dungal, 1944).

Complete protection should be aimed at in certain circumstances Thus, the following types of case should be injected with serum early in the incubation period feeble children, those suffering from another disorder, children under 3, particularly during cold weather

The production of attenuated measles is the most satisfactory because children develop an active immunity Serum is usually given between the 6th and 9th days after exposure The modified attack is characterized by fever, slight catarrh, and a sparsely distributed rash The rash is papular and occurs on the face and rarely the limbs. Koplik's spots are not found and the illness only lasts for about 24 hours There is not much information available regarding the after-history of persons who have suffered from modified (sero-attenuated) measles, but Townsend (1936) recorded that no measles developed in 32 cases who had suffered from modified measles 10 years before

Dosage Varying schemes have been proposed for calculating the dosage (Report of L.C.C., 1938, Morales and Mandry, 1930, Burnet, 1935, Brincker, 1936, Stillerman, Marks, and Thalhimer, 1944). The Medical Research Council (1944) in Britain recommended the following doses for children under 3, for protection, given within 5 days of exposure convalescent serum 5 c c, adult serum 10 c.c.,

hicles, parties, and playgrounds In fact, the value of prophylactics should be estimated on the results of inoculating home contacts They found that the greater the hygienic state of the home the more efficient became the injection of prophylactics An especially important factor was found to be the possibility of isolating the case as early as feasible. In homes of poor hygiene, they found that the larger the dosage of prophylactic the higher the rate of complete protection

4. Gamma globulin.

In the future, as supplies become available, undoubtedly the prophylactic of choice will be the gamma globulin fraction of plasma prepared by Cohn *et al* (1944) Already a number of favorable supe-
riority (Greenberg, Frant, and Rurstein Jen-
nings, and Janeway, 1944, Stokes, Mar 945)
Janeway (1944) recommends the intramuscular injection on the 5th day after exposure of 0 1 c c to 0 075 c c per lb body weight for complete protection, 0 025–0 02 c c on the same day will attenuate

Reactions after the use of gamma globulin are rare, and it is probable that it can be heated sufficiently to destroy the icterogenic agent

77 3 per cent. (*Report*, *1938*). It has been suggested that the potency of placental extract (*vide infra*) is dependent on its content of serum globulin

Whole blood. The use of whole blood (citrated), e g., from a parent, has been recommended by various workers in lieu of immune serum (Rietschel, 1921, Bader, 1929, Stewart, 1932, Lord, 1933, Culbert, 1938, Morley, 1945). As a dose some 10–20 c c should be injected intramuscularly The results seem to be as good as those obtained by other methods

3. Placental extracts.

It has been discovered in recent years that an extract prepared from human placentas has an action comparable to that of convalescent serum The introduction of this substance is largely due to the work of McKhann and his colleagues Thus McKhann and Chu (1933 *a*) reported that placental protein extracts contained antibodies to diphtheria toxin, to the erythrogenic streptococcal toxin, to poliomyelitis virus, and had a prophylactic effect in measles They recommended intramuscular injections of extract in the incubation period for protection or attenuation These observations have been confirmed repeatedly (McKhann and Coady, *1934*, McKhann, Green, and Coady, *1935*, Levitas, *1935*, Eley, *1935*, McKhann *et al*, 1935–6, Chu and Chou, 1935–6, 1936, Huber, 1936, McGavran, 1936, McKhann, 1937 *a*, *b*, Goldstein, Eisenoff, and Blauner, 1937, Rohr, 1938, Gunn, 1938 *b*, Huber and Kurz, 1938, Bundesen *et al*, 1940, Denhoff, 1940, Peragallo, 1940, Lyall and Murdick, 1941, Goldstein, 1942, Greenberg, Frant, and Rutstein, 1944).

Extraction. The active principle can be extracted from placentas by 2 per cent. sodium chloride and refined by precipitation with ammonium sulfate (McKhann and Chu, 1933 *b*) Methyl alcohol precipitation is also effective (Chu and Chou, 1935–6, 1936, Chu and Liu, 1944) Strean *et al.* (1941) prepared a globulin solution from blood from the placental end of the cord Thalhimer and Stillerman (1939) found protective substances in ascitic fluid and its globulin fraction

Titration In view of the fact that placental extract contains diphtheria antitoxin as well as measles antibody, it has been suggested that the extract be titrated by estimating its content of this antitoxin in units (Karelitz, Greenwald, and Klein, 1934–5)

The dosage of placental globulin for injection may be calculated by comparing its diphtheria antitoxin titer with that of the pooled placental blood, which has the same antitoxin titer as the mother's blood (Karelitz and Greenwald, 1934–5; Karelitz, Greenwald, and Klein, 1937 *a*, *b*) Thus, if the placental globulin gives twice as high an antitoxin reading as placental blood, then one would inject only half as much as would be the case with human serum

Rake (1939) titrated the antibody content against swine influenza virus

Administration The dose of dried protein extract should be 0 02 to 0 025 gm. per kilo body weight (Chu and Chou, 1936) The extract is usually administered intramuscularly, but it has been reported that absorption occurs after oral administration (Robinson and McKhann, 1935, McKhann *et al*, 1935–6)

Results Most observers have expressed their satisfaction with placental extract, and have regarded it as efficient as convalescent serum in prophylaxis or seroattenuation (see *J Amer med Ass*, 1938) Some observations of McKhann (1937 *b*) show, however, that the immunity conferred is relatively short-lived, apparently not much over 2 to 3 weeks (see also Parish, 1938), Gallagher (1942) also had disappointing results Karelitz and Karelitz (1938) drew attention to an important factor that largely controls the efficacy of placental extracts, or other prophylactic substances That is to say, the type of exposure to infection must be considered, for they found that infection disseminated in the following sources was so irregular that no true estimate of the value of prophylactics injected into contacts could reasonably be made hospital and institution wards, nurseries, schools, public ve-

rise of temperature 48 hours after defervescence, with a return of constitutional symptoms

The rash may be accompanied or followed by a hemorrhagic diathesis and purpura (Strom, 1940, Fox and Walton, 1946, Magnusson, 1946).

CONGENITAL LESIONS DUE TO RUBELLA

It has been reported only of recent years that babies born to women who contract rubella in the early months of pregnancy commonly show congenital defects

The first observations on this point were made by Gregg in Australia in 1941 (Gregg, 1942). Since then, numerous other cases have been reported from Australia, America, and elsewhere (Swan *et al*, 1943, 1944, Erickson, 1944; Evans, 1944, 1947, Reese, 1944; Rones, 1944; Swan, 1944; Albaugh, 1945, Altmann and Dingmann, 1945, Carruthers, 1945, deRoeth and Greene, 1945, Greenthal, 1945; Gregg, 1945, Krause, 1945; Long and Danielson, 1945; Perera, 1945, Fox and Bortin, 1946, Prendergast, 1946, Winterbotham, 1946) The defects that have been noted are cataract, micro-ophthalmia, uveitis, dacryostenosis, glaucoma, retinal pigmentation, strabismus, deaf-mutism due to loss of cochlear function, mainly from lack of development of the organ of Corti, cardiac lesions such as septal defects and patent ductus arteriosus, microcephaly, cerebral agenesis, and mental retardation, dental abnormalities such as retarded eruption, enamel hypoplasia, and caries, talipes valgus, spina bifida, and cleft palate, general physical retardation, obliteration of bile ducts, cryptorchism, hypospadias, and inguinal hernia, anemia and purpura

Infection appears to be most dangerous in the first 2 months of pregnancy, and probably nearly every baby will show some defect Infection in the third month will produce lesions in about half the babies. Probably attacks of rubella in the latter part of pregnancy do not cause congenital lesions. It does not appear that severe attacks are more dangerous than milder ones.

Swan (1944) studied the pathological features of some cases, and described patent ductus arteriosus, patent foramen ovale, and deficient interventricular septum The lenses showed necrosis of the nuclear portion The lungs showed bronchopneumonia Foci of degeneration were found in the liver. Fibrosis of the glomerular capillaries was also observed

Apparently, congenital defects were not attributed to rubella before about 1939, and it seems as if the virus may have undergone a mutation to a more invasive type in recent years It also seems as if these lesions are much commoner after rubella than after other exanthemata.

Findings of the Australian Committee A special committee examined this question, and reported substantially as follows (Director General of Health, Commonwealth Dept of Health, 1945)

1. That cases of congenital defects following maternal rubella during pregnancy occurred previous to 1940, but the relationship between maternal infection and the congenital defect was not recognized,

2. That it is impossible to estimate the number of pregnant women and subsequent children affected as a result of the epidemic of 1940,

3. That apparently children are not affected when the maternal infection occurs after the 4th month,

4 That the defects have been deaf-mutism, eye and heart disease, and possibly mental defect, and that the first 3 defects may occur singly or in combination,

5. That there is no relationship between the severity of the maternal infection and the nature of the defect

CHAPTER XXIII

GERMAN MEASLES (RUBELLA)

CLINICAL FEATURES

THE ILLNESS may be *initiated by a prodromal period a day or so before the appearance* of the rash, and is characterized by cough, sore throat, and enlargement of the glands in the neck.

The rash usually appears first on the face, but rapidly spreads. The constituent macules are smaller and less elevated than those of measles The eruption seldom lasts more than 36 hours Some catarrh usually persists during the eruptive phase, and the temperature is slightly raised. One of the most characteristic features is the presence of enlarged cervical, and often axillary, lymph nodes.

Another characteristic feature is the appearance of an absolute lymphocytosis Hynes (1940) carried out a special study of the blood picture, and made the fol- [illegible] his patients had an absolute neutropenia which [illegible] after the 10th day, a third showed an absolute [illegible] lymphopenia at onset changed to an absolute lymphocytosis after the 5th day. He usually found Turck cells to be numerous, they reached their maximum about the 4th day Plasma cells were present in up to half his patients in the first week. The leukocyte count can thus distinguish between rubella and scarlet fever, but not between rubella and measles. The differential diagnosis between rubella and glandular fever may be difficult and depend on the sheep cell agglutination test (Deumié, Brumpt, and Thomas, 1940–41).

COMPLICATIONS

Nervous Complications

Between 50 and 100 cases of severe nervous complication have been described The features are those of meningo-encephalitis, which develops between 1 and 6 days after the rash, usually about the 5th day of illness (Owen and Greenaway, 1940, Bradford, 1943, Falger, 1944, Wingo, 1945). Margolis, Wilson, and Top (1943) described 14 cases, and reviewed 34 from the literature They gave the following description the earliest complaints are headache, vomiting, stiffness, and pain in neck and extremities The reflexes are absent, unequal, or exaggerated Speech defects and muscular twitchings may occur.

In severe cases there are convulsions and coma. The course of the illness is usually short In their series, 4/14 died within 3 days of onset, and in previous cases 6/34 died

The CSF shows a marked increase of protein, with less marked increase of lymphocytes Margolis, Wilson, and Top found that the average count was around 90 cells per c.mm.

Only a few reports on the pathological features have appeared Margolis, Wilson, and Top found edema of the brain, there was perivascular infiltration with plasma cells, lymphocytes, or mononuclears Demyelination was not found, but there was nerve cell damage Capillary hemorrhages were found in the floor of the 4th ventricle.

Myelitis may follow rubella (Morris and Robbins, 1943). Neuritis has been recorded (Harrison, 1940, Hodges, 1940, Sprott, 1940).

Other Complications

Rheumatic complications have been described (Murray, 1941) Bennett and Copeman (1940) studied a number of cases in soldiers. There were transient joint

ably develop in convalescence Pooled plasma has been used as a prophylactic, and Barenberg *et al* (1942) claim good results

A proportion of monkeys convalescent from experimental infection proved immune to reinoculation (Habel, 1942).

6 That if the maternal infection occurs after the 2nd month of pregnancy, there is less likelihood of eye disease;

7. That a large number of the affected children are below normal birth weight,

8. That the majority of the children are below average weight for age, and that they show a degree of microcephaly, and their general physique is below standard;

9. That many of the children are late in sitting up and walking, and difficulties in feeding are common,

10. That during the first few years of life, signs of general instability of the nervous system of the children are common,

11. That the deafness is not absolute, and the apparent improvement in hearing about the 2nd half of the 4th year is secondary to improvement in the power of concentration;

12 That the main dental abnormality is retardation of eruption, but that at 3½ years all the children had a full complement of teeth;

13 That very few of the children are mentally defective though many are mentally retarded, the majority of the children are educable, and will be fit to earn their own living, following appropriate education,

14 That there is no evidence to show that the occurrence of rubella during pregnancy has any harmful effects on the mother.

DISTRIBUTION OF THE VIRUS

Habel (1942), by monkey inoculation, found virus in the blood up to 30 hours after the appearance of the rash, nasal washings were positive up to 24 hours He also isolated virus from these sources in a case without a rash.

EPIDEMIOLOGY

The incubation period varies from 5–21 days, with 14 days as the average.

Although predominantly a disease of childhood, adults are attacked more commonly than occurs with most other exanthemata Outbreaks among students and service personnel are not unusual (Wildman and Teasey, 1940)

There is usually a seasonal prevalence in spring and early summer.

The disease is presumably spread by droplets, as virus has been recovered from the nose The case is probably infective for only a few days, from shortly before until shortly after the appearance of the rash Smith (1947) has found it safe to allow return to school after only 4–5 days away

PROPERTIES OF THE VIRUS

The infection has been transmitted to children by inoculation of filtered nasal washings subcutaneously (Hiro and Tasaka, 1938).

The rhesus monkey (*Macacca mulatta*) has been found to respond to the inoculation of human blood or nasal washings by developing a mild illness (Habel, 1942). There is a leukopenia after an incubation period of 8 days. Fever and lymphocytosis follow 2 days later Then there develops a macular rash on the face, chest, abdomen, and thighs Animals can be infected by the nasal, subcutaneous, intraperitoneal, or intravenous routes Virus can be found in the monkey's blood at the time of the rash, and in the period of leukopenia and fever in those animals that do not develop a rash

Habel (1942) was able to pass the virus through the chorio-allantois, no obvious lesions were produced, but membrane suspensions were pathogenic to monkeys He found no evidence of cross immunity with measles virus

IMMUNITY

Second attacks may occur, but are not common It is probable that immunity may be acquired following subclinical attack Virus neutralizing antibodies prob-

sions (cytoplasmic and nuclear) have been described in epithelial cells. (Sohier and Jaulmes, 1939, Sohier and Nabonne, 1939; Sohier and Levrat, 1945).

Cytological examination of the saliva shows a few leukocytes and epithelial squames from Stensen's duct. There is no abnormality in the fermentative power of the saliva (De la Prade and Loiret, 1919 *b*). The calcium and chloride contents increase for the first fortnight or so (Rocchi, 1929, 1930).

The femoral glands may be involved (Schmidt, 1945).

Parotitis, and more especially involvement of the submaxillary glands, may be complicated by edema of the tissues of the anterior wall of the thorax and sometimes abdomen (Barker, 1943; Rappaport, 1943, Gellis and Peters, 1944; Chrysanthis, 1946).

2. Orchitis.

This is probably the second commonest manifestation of mumps, or alternatively, the commonest complication of parotitis. Numerous authors have described the condition and only comparatively few can be mentioned by name (Hamilton, 1790; Dukes, 1900; Smith, 1912; Feiling, 1914–15; Capitan, 1918; Radin, 1918; Dumitresco, Jonnesco, and Chiser, 1932; Manca, 1932; Bieberbach and Vibber, 1933; Huber and Lièvre, 1935; Montgomery, 1936, Ohlmacher, 1936; Zax, 1937). In addition, the subject has been reviewed by Wesselhoeft (1920) and more recently by Stengel (1936). The following account is largely based on that of Stengel. The virus probably reaches the testis from the blood, although it was at one time suggested that the infection was carried to the urethra by infected hands (Sailer, 1919–20). Most agree that the body of the testis is mainly involved (i.e., orchitis) with a degree of accompanying epididymitis. Feiling (1914–15) holds, however, that epididymitis is primary.

Predisposing causes. The fact that the testicle is constantly exposed to minor traumata has been held to account for the localization of the virus therein. It is doubtful whether this factor plays a part, because although Dukes (1900) treated 30 boys by absolute confinement to bed for 8 days, 20 per cent. developed orchitis. Dukes's observation has been confirmed by many others. It seems to be established, however, that undue sexual activity is a definite predisposing cause (see Bardachzi and Barabas, 1920).

Incidence. From a review of 1,000 cases of parotitis Stengel concluded that approximately 18 per cent. are complicated by orchitis. The disease is predominantly one of puberty and adolescence; young soldiers appear to be frequently attacked by this complication. During the first and second World Wars, mumps, and especially orchitis, was a serious cause of loss of manpower. A number of authors alluded to this question in the second World War (Gordon and Heeren, 1940, Wesselhoeft and Walcott, 1942, Dermon and Le Hew, 1944, McGuinness and Gall, 1944, Potter and Bronstein, 1944; Candel, Wheelock, and Grimaldi, 1945).

Time of onset. Orchitis usually develops about 4 to 7 days after the onset of the parotid swelling. A number of well-authenticated cases of primary orchitis have, however, been recorded (e.g., by Bieberbach and Vibber, 1933, Montgomery, 1936, Ohlmacher, 1936, Zax, 1937, 1943; Hild, 1938, Coe, 1945; and see Stengel, 1936) In such cases help can be derived from the CFT (see below).

Course The disease occurs 2 to 3 times more commonly unilaterally than bilaterally, and if the other testicle does become affected it usually does so a day or so after the first (Stengel) The temperature often rises with the onset of orchitis and there is a general febrile reaction. The organ rapidly swells to several times its normal size and is acutely tender and painful; there may be a slight urethral discharge. The pain may be so severe as not to be relieved even by morphia. In some cases operation with incision of the tunica has been performed. The blood usually shows a lymphocytosis. The affected testis frequently atrophies and this may be due to an acute hydrocele strangulating the testis (Burhans, 1945). Sterility has

CHAPTER XXIV

MUMPS (EPIDEMIC PAROTITIS)

AN ACUTE infectious disease *characterized by swelling of the parotid glands has* been known since the days of Hippocrates (see Gordon, 1914, Hansen, 1934). In later times Hamilton (1790) made a special study of the condition in Norfolk (England) and clearly showed that mumps was more than a simple condition causing parotitis, as it might involve the testicles as well. French workers have stressed the frequency of nervous manifestations.

Earlier attempts to prove that the causal agent was a cultivable organism were unconvincing. That the etiological agent was in fact a filtrable virus was suggested by Granata (1908 *a, b,* and see Kolle and Wassermann, 1913), but Gordon (1914) was the first to show clearly that the disease could be transmitted to animals, thus laying the foundation for later work. Wollstein (1916, 1918, 1921), Findlay and Clarke (1934), Johnson and Goodpasture (1934, 1935, 1936 *a, b*), and others (*vide infra*) have proved that the causal agent is filtrable and transmissible to animals

A useful review of the literature on mumps has been published by Rolleston (1932).

CLINICAL FEATURES

The term "mumps" is frequently regarded as synonymous with "epidemic parotitis," but this is somewhat inaccurate. Epidemic parotitis is certainly the commonest manifestation of infection by the virus of mumps, but it is not the only one. The other manifestations of mumps are orchitis, meningo-encephalitis, pancreatitis, and ovaritis, these most commonly follow the development of a parotitis by some 5 to 7 days and in such cases may be regarded as complications of epidemic parotitis In other cases, however, these manifestations may either precede parotitis or occur independently.

We prefer, therefore, to use the term "mumps" to include the various manifestations mentioned, and to restrict the term "epidemic parotitis" purely to involvement of the parotid glands

Manifestations of Mumps

1. Parotitis, and inflammation of the submandibular glands.

Following an incubation period of 18 to 21 days there may be a prodromal period of 12 to 36 hours in which headache, posterior pharyngitis, and general nonspecific pyrexial symptoms occur. The onset of the disease is characteristically sudden, with pain in one or both parotid glands. Sometimes the submaxillary and sublingual glands may be involved, with or without affection of the parotids (Smith, 1943) The parotid rapidly swells, the hollow below the ear becomes filled up, but the gland is not usually tender, and the overlying skin is not discolored. There is very considerable pain on attempting to open the mouth, which is usually very dry The orifice of Stensen's duct is often bright red.

General pyrexial disturbances are noted for a few days, and headache may be severe. The spleen may be enlarged (Greene and Heeren, 1937) The majority of patients feels acutely uncomfortable for a few days, but the swelling and accompanying malaise usually disappear in 7 to 10 days In bilateral cases both glands may be involved *de novo*, but more commonly the second gland becomes swollen a few days after the first.

Specimens may be taken with a suitable aspirator direct from the duct, inclu-

in which the virus of lymphocytic choriomeningitis cannot be found, are due to mumps (Howard, 1919, Paddock, 1932, Armand-Delille *et al.*, 1937, Jersild, 1942, Applebaum, Shrager, and Paff, 1945, Coe, 1945; J. H Smith, 1945). In such cases the diagnosis may be confirmed by the CFT on blood or cerebrospinal fluid (Kane and Enders, 1945, Henle and McDougall, 1947).

Symptoms The commonest symptoms are referable to an inflammatory meningeal reaction, headache being usually very severe; the patient is anxious, excited, restless, and even delirious Convulsions and contractions may be noted, the temperature is usually raised Many authors have noted evidence of severer parenchymatous damage due to an encephalitis Thus the following symptoms have been recorded mania and mental confusion (Urechia and Elekes, 1936), cerebral diplegia, dementia, and choreo-athetosis (Stroé and Chiser, 1932), aphasia, paralyses, and hemiplegia (Monro and Healy, 1883, Lannois and Lemoine, 1886), symptoms of acute midbrain disease (van Bogaert and Meunier, 1938). The diagnosis of encephalitis lethargica may easily be made until the appearance of parotitis gives the clew (Bedingfield, 1927). The cases in which meningitis is the main feature are often followed by orchitis

Gordon (1914) [illegible] which most of the children died [illegible] time of onset The patients were [illegible] and eventually became comatose. [illegible] pupils were dilated, and there were muscular movements of twitchings or convulsions Lymphocytosis occurred in the blood and cerebrospinal fluid Pathologically the central nervous system was remarkably little involved, although it showed some congestion and early nerve cell degenerative changes The salivary glands showed an acute interstitial inflammatory reaction.

4. Pancreatitis.

This manifestation is comparatively rare, nevertheless a number of cases have been recorded (Sabrazès, Broustet, and Beaudiment, 1927, Spicer, 1933, James, 1933, Greene and Heeren, 1937, Herson, Christopoulos, and Coghill, 1944). Farnam (1922) and Brahdy and Schaeffer (1931) have reviewed this subject, and the following account is largely based on their works.

The disease usually develops some 5 to 11 days after the onset of parotitis, although rarely the pancreatitis may precede In fact, it was suggested in 2 cases that mumps pancreatitis occurred without any parotitis (Friedjung, 1928) The patient is febrile (up to 103° to 104° F.), nauseated, and complains of headache, abdominal pain, and tenderness Vomiting is not a prominent feature, the bowels are constipated and there is no steatorrhea In very severe cases the urine may contain sugar, as well as giving a high reading in the diastase test Although very rare, a few cases of diabetes following mumps pancreatitis have been recorded (see Patrick, 1924, Couronne, 1927, Rennie, 1935). These cases are often of severe type and terminate fatally Apart from the development of diabetes, mumps pancreatitis seldom proves fatal

5. Ovaritis.

This manifestation is the rarest of all and in no way corresponds in frequency to the parallel condition of orchitis.

The manifestation of ovaritis was [illegible]

[illegible] between lower abd[illegible] [illegible] the infection is associated with a high temperature and [illegible] ingitis may readily be made app[illegible] onset of parotitis, but may has [illegible] 1936) Suppurative ovaritis [illegible] 1934)

been held to be unusual owing to the rarity of bilateral involvement (see Capitan, 1918, Bénard, 1928), but Seguy (1942) estimates that 4 per cent. of cases of sterility are due to mumps. There is probably no direct relationship between orchitis and tumor growth (Gilbert, 1944).

3. Meningo-encephalitis.

There is probably a lymphocytosis in the CSF in most cases of mumps, whether there is clinical evidence of nervous involvement or not, the term "latent meningitis" has been used to describe such cases, where the diagnosis can only be made by examining the fluid pathologically, counts up to 2,500 per c mm. have been found in declared or [illegible] protein is also increased (Monod, 1902; Chauffard [illegible] 4, 1905; Feiling, 1913, Silwer, 1936, Finkelstein, [illegible] oyer, 1938, Schonfeld, 1939, Bang and Bang, 194 [illegible] 1946). Sometimes the fluid may be virtually normal in declared cases of nervous involvement (Halcrow and Wang, 1945).

Various theories have been advanced to account for the development of meningo-encephalitis (see Montgomery, 1934):

(*a*) The cerebral condition is merely a passive congestion from compression of the jugular vein. This theory can attract little attention as it appears to be a quite inadequate explanation of the observed facts

(*b*) The condition is due to the lodgment of infected emboli from an endocarditis, but no such condition has been found post mortem

(*c*) It has been suggested that mumps is primarily a disease of the central nervous system caused by a neurotropic virus (Philibert, 1932, Dutrey, 1936) The virus [illegible] tis We feel [illegible] al evidence. [illegible] of a number of sites, such as the meninges, the parotids, the pancreas, the testes, or the ovaries This view may be correct, but it is difficult to understand why a blood-spread should be invoked to explain the common primary parotitis, for it is well known from both animal and human experiments that infection occurs regularly after application of virus to Stensen's duct (*vide infra*)

We think that the central nervous system is most likely to be involved by spread along axonal paths, in cases of primary meningo-encephalitis probably along the olfactory nerves or nerves from the nose or pharynx; in secondary cases perhaps along the facial and other nerves in relation to the salivary glands While the term "meningo-encephalitis" is usually applied in a general way, in some cases the symptoms are predominantly meningitic, and in others encephalitic

Attention was first drawn to the occasional involvement of the central nervous system in mumps by Gallavardin (1898). Since that time, numbers of authors have described cases (Monro and Healy, 1883, Lannois and Lemoine, 1886, Chauffard and Boidin, 1904, Dopter, 1904, 1905, Feiling, 1913, Bedingfield, 1927, Holtz, 1931, Paddock, 1932, Dumitresco, Jonnesco, and Chiser, 1932, Stroé and Chiser, 1932, Kousmine, 1934, Andrieu and Passa, 1935, Urechia, 1936, Silwer, 1936, Auvray, [illegible] Smith 1937 Finkelstein, 1938, Fuhrmann, 1938, Glanzmann, [illegible] 1939, 1940, Stewart and Edwards, 1939, Tabor [illegible] 41, Ahlberg, 1942, Levison and Thordarson, 1942, Carleton, 1943, Feer, 1943, Candel *et al*, 1944 *b*, Herson, Christopoulos, and Coghill, 1944, McGuinness and Gall, 1944, Steinberg, 1944)

Time of onset. The symptoms usually develop from 4 to 7 days after the onset of the parotitis, when this swelling is beginning to subside Cases have been recorded where meningo-encephalitis preceded the parotitis or orchitis by a few days (Bedingfield, 1927, Urechia, 1936, Urechia and Elekes, 1936, Auvray, 1937, Harris and Bethel, 1938, Snapper, 1940) Some cases of aseptic meningitis without any parotitis,

Myocarditis has been described (Wendkos and Noll, 1944, Rosenberg, 1945 *a*, *b*, Felknor and Pullen, 1946).

A case of pituitary basophilism following parotitis with orchitis has been recorded (Huber and Lièvre, 1935). Another case in which pituitary affection was probably present was recorded by Lesné, Dreyfus-Sée, and Lièvre (1930).

Although mumps very rarely occurs during pregnancy, the outlook is serious. Thus Dutta's (1935) case died from acute nephritis, Moore's (1931) patient was delivered of a macerated fetus, while another case died from nephritis and eclampsia (Micheleau, 1927).

CLINICAL PATHOLOGY

The blood. Various authors have examined the blood in mumps, and the following facts seem to be fairly well accepted (Feiling, 1913, 1914–15; Jahn, 1928, Matsumoto, 1936; Montgomery, 1936): (1) There is a relative or absolute lymphocytosis, counts ranging up to about 15,000 cells per c mm, of which 45 per cent. may be lymphocytes (2) This lymphocytosis may be found from the 1st to the 14th days of the illness (3) The examination of the blood may be of value in the differential diagnosis from secondary (septic) parotitis.

The blood sedimentation rate is raised in orchitis (Candel *et al.*, 1944 *a*). The blood diastase is usually increased (Faergeman, 1943, Murphy, Bozalis, and Bieri,
1 lebaum, 1944, Fennel, 1944;
C
Dunlop (1933), a reading
of 30 to 200 units per c.c. may be obtained, as high as would be found in other
ty
ar
fr
T

lymphocytosis, this becomes still more definite in cases of meningo-encephalitis (see above).

DISTRIBUTION OF THE VIRUS IN INFECTED PERSONS

It is generally agreed that virus can only be isolated from the saliva of cases of parotitis for 2 to 4 days after onset. On epidemiological grounds, however, it is probable that the virus actually appears in the saliva 3 to 4 days before the onset of clinically apparent parotitis The virus has been found in the cerebrospinal fluid of a case of meningitis by Lavergne *et al.* (1937 *a*, *b*), and Swan and Mawson (1943), as well as Henle and McDougall (1947), also in the blood of a severe case by Wollstein (1918).

MORTALITY

The mortality from mumps is remarkably low, the majority of deaths occurring under 5 years and especially under 1 year of age. The average death rate is probably about 3 per million living. The majority of deaths are due to meningo-encephalitis, pancreatitis, or a superimposed complication such as nephritis

PATHOGENESIS

Parotitis can be reproduced in monkeys by injecting the parotid ducts, and in many cases by directing a spray of infective material at the duct orifices (*vide infra*) This experimental work has made it almost certain that, in man, epidemic parotitis follows the introduction of infected material into the mouth. Having reached the parotid and caused infection, the virus may enter the blood and localize in the meninges, testes, pancreas, or ovaries. Virus may reach the central nervous

COMPLICATIONS

Nervous Complications

Various lesions of the nervous system may occur which are to be regarded as true complications rather than as evidence of a primary localization of the virus (see Glanzmann, 1938).

Myelitis. Symptoms referable to the cord are rare, but a definite case of transverse myelitis was recorded by McKaig and Woltman (1933). Fortney (1937), Lemierre and Morin (1938), Lancaster (1938), Dénéchau (1939), McGuinness and Gall (1944); and Lightwood (1946) have also reported cases.

Ocular complications. Optic neuritis may occur on recovery from mumps (see Swab, 1938). A case of Young's (1933) became completely blind, but recovered full vision later. A temporary recoverable amblyopia may occur during convalescence (Hatry, see Gordon, 1914).

Other ocular nerves may also be paralyzed and some cases of Butler and Wilson (1937) illustrated such involvement. These ocular paralyses are probably due to a meningoradiculitis and not to a more central effect

Bonnet (1938) claimed that eye changes in mumps should be considered, not as complications, but as true manifestations, in the same way as are orchitis and meningitis. Among the lesions that he refers to are conjunctivitis, dacryocystitis, iritis, and keratitis.

Auditory complications. As long ago as 1898 Gallavardin collected some 50 cases of deafness due to mumps, and noted the presence of Ménière's syndrome in some of these. Boot (1908) also reviewed a somewhat similar number of cases, and found that this deafness was due to involvement of the cochlea, or the semicircular canals, or more commonly of both. Hubbard (1915) estimated that up to 5 per cent. of deaf-mutism in the United States was caused by mumps.

Herpes zoster. The presence of meningoradiculitis would probably account for the occasional record of zoster eruptions developing along the distribution of various nerves, e.g, the trigeminal (Sicard, 1905).

Peripheral neuritis. Paralysis from polyneuritis is rare, and may be due to a meningoradiculitis at the site of exit of the roots from the spinal column (Gallavardin, 1898, Thiriet, 1928–9, Collens and Rabinowitz, 1928, Church, 1946) Facial paralysis has been recorded (Dopter, 1904, Nemlicher, Tchernikow, and Solomonowa, 1932), this suggests that the virus may enter the nerve in the neighborhood of the parotid gland and spread centripetally. Harris (see Harris and Bethell, 1938) saw a case of paralysis of the serratus magnus due to involvement of the long thoracic nerve

Appendicitis

The onset of a serious, often gangrenous, acute appendicitis, about a week after parotitis, has been recorded on a few occasions (Sandler and Finne, 1932, Donnelly and Oldham, 1933, Finch, 1933, Leenhardt and Barnay, 1937) The obvious importance of such cases is that operation may be delayed in the mistaken impression that one is dealing with a mumps pancreatitis

Other Complications

A definite acute nephritis with hematuria, casts, and albumin may occur and contribute to a fatal issue (Feiling, 1914–15, Sabrazès, Broustet, and Beaudiment, 1927; Dutta, 1935).

Local parotid suppuration is a rare sequel (see Rundle, 1929). Upper respiratory tract infection may occur (Herson, Christopoulos, and Coghill, 1944) Keratitis has been reported (Danielson and Long, 1941)

It has been suggested that endocarditis may complicate mumps (Sciaux, 1935)

Myocarditis has been described (Wendkos and Noll, 1944; Rosenberg, 1945 *a*, *b*, Felknor and Pullen, 1946).

A case of pituitary basophilism following parotitis with orchitis has been recorded (Huber and Lièvre, 1935). Another case in which pituitary affection was probably present was recorded by Lesné, Dreyfus-Sée, and Lièvre (1930).

Although mumps very rarely occurs during pregnancy, the outlook is serious Thus Dutta's (1935) case died from acute nephritis, Moore's (1931) patient was delivered of a macerated fetus, while another case died from nephritis and eclampsia (Micheleau, 1927).

CLINICAL PATHOLOGY

The blood. Various authors have examined the blood in mumps, and the following facts seem to be fairly well accepted (Feiling, 1913, 1914–15, Jahn, 1928, Matsumoto, 1936; Montgomery, 1936)· (1) There is a relative or absolute lymphocytosis, counts ranging up to about 15,000 cells per c mm., of which 45 per cent. may be lymphocytes. (2) This lymphocytosis may be found from the 1st to the 14th days of the illness. (3) The examination of the blood may be of value in the differential diagnosis from secondary (septic) parotitis

The blood sedimentation rate is raised in orchitis (Candel *et al.*, 1944 *a*). The [illegible] Murphy, Bozalis, and Bieri, [illegible] 'cbaum, 1944; Fennel, 1944, [illegible] Dunlop (1933); a reading of 30 to 200 units per c c. may be obtained, as high as would be found in other types of acute pancreatitis. This reaction is found in uncomplicated cases of mumps and is not dependent on a clinically apparent pancreatitis. The test becomes positive from the second day and persists when the swelling of the parotids has subsided. The urinary diastase probably derives from the parotid gland.

The cerebrospinal fluid. Even in uncomplicated cases of mumps there is a lymphocytosis, this becomes still more definite in cases of meningo-encephalitis (see above).

DISTRIBUTION OF THE VIRUS IN INFECTED PERSONS

It is generally agreed that virus can only be isolated from the saliva of cases of parotitis for 2 to 4 days after onset. On epidemiological grounds, however, it is probable that the virus actually appears in the saliva 3 to 4 days before the onset of clinically apparent parotitis The virus has been found in the cerebrospinal fluid of a case of meningitis by Lavergne *et al* (1937 *a*, *b*), and Swan and Mawson (1943), as well as Henle and McDougall (1947), also in the blood of a severe case by Wollstein (1918).

MORTALITY

The mortality from mumps is remarkably low, the majority of deaths occurring under 5 years and especially under 1 year of age. The average death rate is probably about 3 per million living The majority of deaths are due to meningo-encephalitis, pancreatitis, or a superimposed complication such as nephritis.

PATHOGENESIS

Parotitis can be reproduced in monkeys by injecting the parotid ducts, and in many cases by directing a spray of infective material at the duct orifices (*vide infra*). This experimental work has made it almost certain that, in man, epidemic parotitis follows the introduction of infected material into the mouth Having reached the parotid and caused infection, the virus may enter the blood and localize in the meninges, testes, pancreas, or ovaries Virus may reach the central nervous

system by centripetal spread along nerves associated with the parotid gland, and it should be recalled that facial paralysis has been described.

It is more difficult to explain those cases in which meningitis, or other manifestation, precedes the parotitis or occurs as the sole evidence of mumps infection Here it is necessary to postulate that the virus enters the body by some route other than the parotid gland. In the case of primary meningo-encephalitis it is not unreasonable to assume that the virus may spread by the olfactory, nasal, or pharyngeal nerves. In the other cases the virus may enter the tonsil and be disseminated to the pancreas, testes, or ovaries by the blood stream.

Mumps virus resembles NDV and influenza viruses in agglutinating red cells (see below). Burnet (1945) therefore suggests mumps virus, like these agents, multiplies in superficial and epithelial cells of the respiratory tract or conjunctiva, and causes initially a subclinical infection This primary invasion produces enough virus to enter the blood and localize in the parotids or other organs

PATHOLOGICAL FEATURES

Remarkably few reports of the changes in the parotids are available for study (*Dopter and Repaci, 1909, Henke and Lubarsch, 1929*). The changes are predominantly interstitial with slight lesions of the excretory ducts. The connective tissue shows a serofibrinous exudate and is infiltrated with leukocytes, mainly perivascularly. The epithelial cells of the ducts show some degenerative changes, and the lumina are filled with necrotic debris and polymorphs Areas of hemorrhage are present

The testis was also examined by Dopter and Repaci as well as by Smith (1912) and Manca (1932) It is greatly enlarged and congested and shows punctate hemorrhages Histologically, there is an irregular involvement of the seminiferous tubules, some of which show degeneration of epithelium and a polymorphic infiltration By contrast, the interstitium is more uniformly affected and shows serofibrinous exudation and edema Numerous leukocytes are found, especially perivascularly. Gall (1947) traced a graded series of lesions from edema and perivascular lymphocytic exudate to a diffuse lymphocytic infiltration of the interstice with focal hemorrhage and destruction of germinal epithelium, with plugging of tubules by epithelial debris, fibrin, and polymorphs He found that in the epididymis changes were confined to the connective tissues

The pancreas has been examined by various workers (Lemoine and Lapasset, 1905, Farnam, 1922, Sabrazès, Broustet, and Beaudiment, 1927) The organ is enlarged, congested, and may show some fat necrosis

Changes in the central nervous system have been described by Maximowitch (1880) and Bien (1913) The brain appears congested and the surface is covered by a serofibrinous exudate, while there may be some destruction of the sheaths of the white fibers in the cortex Donohue (1941) found perivascular demyelination, as in other postinfective encephalitides

EPIDEMIOLOGY

Mumps occurs in all parts of the world In "virgin soil" the infection tends to be severe (Herson, Christopoulos, and Coghill, 1944) The majority of cases occurs either in childhood or adolescence A case has been recorded at the age of 80 (Paraf and Orestein, 1940) The disease is very prevalent among young soldiers and in residential schools (Medical Research Council, 1938) It appears that the disease does not tend to spread widely throughout a school The epidemic is usually drawn out, however, and occupies the greater part of a term.

In Norway it has been shown that mumps epidemics occur regularly every 8 to 10 years (Gundersen, 1927) In Britain, at any rate, the disease occurs more commonly in the autumn and spring than at other times Mumps appears to obey the special "epidemic rules" of Petersen (Heiberg and Petersen, 1946)

The disease is almost certainly spread by infective droplets of secretion, the virus is present in the saliva, from probably a few days before the onset of parotitis until a few days after The "striking-distance" of mumps is not very considerable, and it is unlikely that the virus has any great resistance to sunlight or desiccation The dissemination of the infection is chiefly due to declared cases, but sufferers from subclinical infections may play some part

As respiratory symptoms are uncommon, it is unlikely that mumps can be regarded as a true air-borne disease (Habel, 1945 *a*). However, Wells (1945) claims that irradiation of class rooms has some effect on incidence

A case of mumps should probably be isolated for 3 weeks In view of the long incubation period, contacts may be quarantined for 1 month It is probably unnecessary to enforce quarantine for the first week following exposure as cases do not usually become infective until at the most 3 to 4 days before the onset of parotitis The regulations of the British Board of Education, as expressed in their *Memorandum* of 1942, require the patient to be excluded from school for 1 week after the subsidence of the swelling Contacts need not be excluded Smith (1947) discusses the procedures to be followed in boarding schools

INVESTIGATION OF THE ETIOLOGICAL AGENT OF MUMPS

1 *Cultivable cocci* In the early days a number of workers reported the isolation of cultivable cocci from the parotid gland or testis (Laveran and Catrin, 1893, Teissier and Esmein, 1906, Korentschewsky, 1907, and see Gordon, 1914, and Kermorgant, 1925 *a*) In view of subsequent work no significance need be attached to these results, the organisms were either commensals or contaminants Those workers who have isolated the virus of mumps have failed to find any organisms in the parotid fluid (Nicolle and Conseil, 1913 *a*, *b*, Johnson and Goodpasture, 1934)

2 *Kermorgant's spirochete* Kermorgant claims to have isolated a spirochete from human lesions which can produce parotitis experimentally (Kermorgant, 1925 *a*, *b*, *c*, 1933) Kermorgant obtained the buccopharyngeal secretion from early cases of mumps and made cultures in anaerobic media The primary cultures were, of course, mixed, one of the organisms being a spirochete On repeated subculture it was eventually possible to obtain the spirochete and a motile bacterium growing together in symbiosis without any other organisms The spirochete was of the refringens type, and could be agglutinated and lysed by mumps convalescent sera The spirochete and bacterium together caused a parotitis in monkeys after injection into Stensen's duct When such cultures were filtered (Chamberland L_2 or L_3) the bacterium did not pass, but the spirochete passed through in a granular or filtrable phase The filtrate reproduced the same lesions as the original culture, including orchitis on intratesticular injection of monkeys On adding some of the motile organism to the filtrate and then culturing, the spirochete reappeared It was also claimed that orchitis developed after intratesticular injection of rabbits

Kermorgant himself was unable to demonstrate the spirochete in the infected

1927), nor in parotid secretions (Johnson and Goodpasture, 1934, Findlay and Clarke, 1934) Further, the spirochaeticidal arsenicals were ineffective in treatment (Molinelli, 1925) Kermorgant's results are not generally accepted, for, although he isolated a spirochete, it is unlikely that it was more than an unimportant commensal of the human mouth

3 *The filtrable virus of mumps* It is now generally agreed that the causal agent of mumps is a filtrable virus Granata was the first to suggest this possibility (1908 *a*, *b*, and see Kolle and Wassermann, 1913) He injected rabbits by various

routes with filtered saliva from human cases, and found that a definite rise of temperature occurred. After intraparotid injection a local swelling developed.

The next advance was made simultaneously by Nicolle and Conseil (1913 *a*, *b*) in France, and Gordon (1914) in England. Nicolle and Conseil injected fluid obtained by puncturing human parotid glands into the parotids of bonnet monkeys. Fever usually developed after the 27th day and in 1 out of 3 monkeys a definite painful swelling of the parotids was noted, the blood showed a lymphocytosis during the febrile period.

Gordon injected rhesus and cynomolgus monkeys intracerebrally with Berkefeld filtrates of human saliva obtained in the first few days of parotitis Some of the animals died on the fourth day with meningeal symptoms Following combined intravenous and intraperitoneal injection, a rhesus monkey developed swollen parotids, but recovered shortly afterward.

The next worker was Wollstein (1916, 1918, 1921) who reproduced parotitis, orchitis, and meningitis in cats

Important results were obtained by Johnson and Goodpasture (1934, 1935, 1936 *a*, *b*) After instillation of saliva into Stensen's ducts of rhesus monkeys a definite parotitis developed. These workers were able to passage the virus for over 10 generations. A number of other authors has been able to isolate a similar virus from cases of mumps (e.g, Findlay and Clarke, 1934, Levaditi *et al*, 1935 *a*, *b*, *c*, Lavergne *et al.*, 1937 *a*, *b*, and see below).

PROPERTIES OF THE MUMPS VIRUS

Human Inoculation

Johnson and Goodpasture (1935) sprayed a suspension of infected monkey's salivary glands into the nostrils and toward the Stensen's ducts of 13 susceptible persons. In 6 cases definite clinical mumps developed, after an incubation period of 18 to 33 days. Monkey-passed virus was used by Stokes *et al* (1946), and introduced in the diet or sprayed over the buccal mucosa, infection was characterized by pyrexia, enlarged parotids, a red orifice to the ducts, headache, and nausea It has also been reported that a laboratory attendant developed mumps after working with the virus (Levaditi *et al*, 1935 *c*).

Animal Experiments

Monkeys.

The following monkeys are susceptible to the virus bonnet, rhesus, and cynomolgus, chimpanzees are very susceptible (Levaditi *et al.*, 1935 *a*) Ceropithecus and cynocephalus monkeys are insusceptible to intraparotid injection (Levaditi *et al*, 1935 *c*). Using intracerebral injection, Gordon (1914) found that cynomolgus monkeys are more susceptible than rhesus Using intraparotid injection, however, it would appear that rhesus monkeys are perfectly satisfactory.

1. *Intracerebral injection* A proportion of monkeys develops meningo-encephalitis after intracerebral injection of infective material (Gordon, 1914, 1927, Lépine, Sohier, and Sautter, 1940, Swan and Mawson, 1943) Virus may be injected intraperitoneally as well to render the results even more certain A day or so after injection the animals become quiet and hang their heads, if touched they are irritable, and the limbs may be rigid In one case Gordon (1914) carried out lumbar puncture and found a pleocytosis of 15,000 cells per c mm with 82 per cent. of lymphocytes.

The animals usually die by the 4th day The pathological features have been described by Gordon (1914) Naked-eye, the meninges, brain, and cord appear congested. Histologically, the pia is infiltrated with lymphocytes The substance of the brain and cord is congested and the gray matter shows petechiae The ante-

rior horn cells may show degenerative changes, and although neuronophagia is not present there is some reactionary gliosis. The cerebral cortical nerve cells may also appear somewhat degenerate. Prolonged search may reveal an occasional focus of perivascular cuffing and more diffuse lymphocytic infiltration in the cortex (Gordon, 1927).

2. *Parotid injection* The virus may be injected into the substance of the gland, through the skin in front of the ear (Nicolle and Conseil, 1913 *a, b*). Alternatively, Stensen's duct may be cannulated and about 2 c c of virus instilled (Findlay and Clarke, 1934, Johnson and Goodpasture, 1934; Levaditi *et al*, 1935 *a*) Immediately following instillation of the duct the gland becomes enlarged, but returns to normal in 2 to 4 days A transient rise of temperature may be noted about 3 days after inoculation. Such changes should not be confused with the significant and specific alterations which occur from the 6th to the 8th day onward. The temperature rises, the blood shows a leukopenia with relative lymphocytosis, and the parotid

The parotitis and tem-

oted that a severer and more general reaction developed, the animals were drowsy, listless, but easily excited The glands were markedly tender.

Later workers have confirmed the susceptibility of monkeys to introduction of virus (human, monkey, or egg) by cannulation of the duct, or direct injection

943, Habel,

1946).

been fully

described (Gordon, 1914; Findlay and Clarke, 1934, Johnson and Goodpasture, 1934, 1936 *b;* Levaditi *et al*, 1935 *a, b, c;* Bloch, 1937). To the naked eye there is considerable edema of the neighboring tissues, and the parotids are enlarged and hemorrhagic.

Histologically, the lesions are of a focal nature. The acini are primarily attacked, and early degenerative changes of the epithelium are shown by swelling and detachment from the basement membrane, the cytoplasm is granular and the nucleus hyperchromatic. Later, the cells become necrotic and mononuclear phagocytes and leukocytes fill the acinar lumen, to constitute a small inflammatory focus. The acinar changes are definitely prior to those in the interstitial tissues, where a serofibrinous and cellular exudate is found, with some petechiae, most marked in the region of the acini, ducts, and vessels The interacinar spaces are widened by the interstitial edema. The cellular elements found in the acini and interstitium are lymphocytes and mononuclear phagocytes, polymorphs are not found It must be emphasized that these acinar changes are focal, and examination of any one slide shows areas at different stages of involvement. The stage of recovery is manifest by disappearance of the interstitial exudate and edema, but an increase of the periductal cellular infiltration The affected acini heal by absorption of debris, without fibrosis.

Inclusion bodies have been described in the acinar cells (Johnson and Goodpasture, 1936 *b*), these are eosinophilic granules measuring up to 4 μ in diameter, and are best seen in cells presenting only swelling In cells showing early necrosis they are smaller and may be multiple.

It has been pointed out by Levaditi *et al* (1935 *b, c*) that normal saliva injected into Stensen's duct produces changes of the same nature as those just described However, the changes produced by mumps salivary specimens are more marked than those produced by normal specimens

3 *Intratesticular injection.* Findlay and Clarke (1934) injected the tunica vaginalis of two rhesus monkeys with infective material Histologically, the tunica was infiltrated with lymphocytes and plasma cells and some of the seminiferous tubules showed degenerative changes

4. *Other routes of injection.* Monkeys may develop parotitis after intravenous (combined with intraperitoneal) injections.

Rabbits.

Granata (1908 *a*, *b*) claimed to have infected rabbits by various routes A rise of temperature followed intravenous and intraparotid injections, and a local swelling followed the latter. Corneal inoculation also gave a positive result, small elementary-body-like granules being found in the epithelial cells These results cannot have been generally confirmed as little or no mention of the susceptibility of rabbits appeared until the work of Lavergne *et al.* (1937 *a*, *b*, 1938, Lavergne and Kissel, 1938). These workers claimed to have found the virus in the cerebrospinal fluid of human cases of mumps meningitis, and in other cases in the incubation period After intrathecal injection rabbits developed a pleocytosis in the cerebrospinal fluid Histologically, lesions were noted in the brain and cord Perivascular cuffing, diffuse and focal cellular infiltration, and diffuse demyelination all occurred

Cats.

Positive results have been recorded by Wollstein, particularly with half-grown animals (1916, 1918, 1921). After intraparotid injection of infective secretion, the glands become swollen in 6 to 7 days, a rise of temperature and leukopenia with relative lymphocytosis accompany this swelling. The virus can be found in the saliva of infected animals Histologically, the gland shows edema of the connective tissue with mononuclear infiltrations, the acinar epithelium is swollen

Intratesticular injection produces a swelling, with accompanying temperature and blood changes, after 6 to 7 days. Histologically, the epithelium is degenerate and there is imperfect spermatogenesis. The interstitial cells are swollen and there is a cellular infiltration between the tubules.

Following intrathecal injection, an aseptic meningitis develops, and lasts for 3 to 5 days The virus is demonstrable in the cerebrospinal fluid Histologically, the changes are slight, the pia is somewhat cloudy, and the vessels congested

Insusceptible animals.

It has not been shown that dogs are susceptible, although this was suggested by Busquet and Laveran (1897). Numerous other animals must have been used in the course of experimental work, but no positive results have been reported

An Interference Phenomenon

It has been reported that a cerebral inoculation of virus in mice interferes with the proliferation of WFI virus (Vilches and Hirst, 1947)

Antigenic Structure

No evidence has been adduced to suggest that different antigenic types of virus exist (Beveridge and Lind, 1946) The virus occurs in the form of elementary bodies associated with infectivity, hemagglutination, and some CF property, and there is also a soluble smaller component retaining some complement fixing power only (see below, Henle, Henle, and Harris, 1947).

Morphology and Filtrability

No definite elementary bodies have been described, but eosinophilic inclusions measuring up to 4 μ have been described in the cytoplasm of acinar cells in the parotid (Johnson and Goodpasture, 1936 *b*)

The virus traverses Berkefeld filters British, V and N (Granata, 1908 *a*, *b*, Gordon, 1914, Findlay and Clarke, 1934, Johnson and Goodpasture, 1934, Levaditi *et al*, 1935 *b*), but it does not pass Chamberland L, filters (Levaditi *et al*, 1935 *b*) Habel (1945 *b*) estimated the size at over 340 mμ

Reaction to Physical and Chemical Agents

The virus is destroyed in 1 hour at 55° C. (Gordon, 1914); Habel (1945 *b*) found 20 minutes sufficient for inactivation It resists freezing for at least 3 weeks, and desiccation from the frozen state for several weeks (Johnson and Goodpasture, 1934; Enders *et al.*, 1945) The virus resists glycerol for several weeks (Findlay and Clarke, 1934; Johnson and Goodpasture, 1934) It is inactivated by formalin, ether, and UVL (Habel, 1945 *b*, 1946).

Infection in the Fertile Egg

A number of workers has found that virus from human material or passed in monkeys grows readily on inoculation in the egg It can be introduced by the following routes, the presence of infection being judged by the occurrence of hemagglutination with yolk or amniotic fluid (see below), or the presence of complement fixing antigen.

1. After inoculation in the yolk sac, virus proliferates locally, but is found most abundantly (after 6–7 days incubation at 34–35° C) in the amniotic fluid, amorphous granules up to 0 5 mm may be found in the yolk (Levens and Enders, 1945, Habel, 1945 *b*, 1946, Beveridge and Lind, 1946, Beveridge, Lind, and Anderson, 1946, Burnet, 1946). Transfer can be carried out with yolk sac suspension or amniotic fluid. The amniotic fluid has a smoky appearance that can be removed by adsorption with fowl cells, and high-speed centrifugation (Beveridge, Lind, and Anderson, 1946).

2. The amniotic route is probably the most susceptible, and can be used for the isolation of virus from human salivary specimens (Habel, 1945 *b*, Beveridge, Lind, and Anderson, 1946, Burnet, 1946, Henle, Henle, and Harris, 1947).

3 Egg passage virus causes infection by the allantoic route; the allantoic fluid produces hemagglutination and contains CF antigen (Habel, 1945 *b*, 1946, Beveridge, Lind, and Anderson, 1946, Henle, Henle, and Harris, 1947). Habel (1946) showed that when allantoic fluid is frozen and thawed, part of the virus adheres to the urate deposit.

The injection of polysaccharide prevents virus growth (Ginsberg, Goebel, and Horsfall, 1947).

4. The chorio-allantoic route can be used, but no definite lesions are produced on the membrane (Rocchi, 1943, Levens and Enders, 1945).

On continued egg passage, virulence for the monkey may lessen (Enders *et al*, 1946 *b*)

HEMAGGLUTINATION

Sources of Hemagglutinin

Mumps hemagglutinin (HA) is found most readily in amniotic fluid after amniotic or yolk sac inoculation (Levens and Enders, 1945, Beveridge and Lind, 1946, Beveridge, Lind, and Anderson, 1946, Burnet, 1946) It can also be detected in yolk fluid (Beveridge, Lind, and Anderson, 1946), and allantoic fluid (Beveridge, Lind, and Anderson, 1946, Burnet, 1946) It occurs in much higher titer in egg fluids than in the allantoic and amniotic membranes (Henle, Henle, and Harris, 1947)

Monkey parotid gland virus does not agglutinate fowl cells, although complement fixing antigen is present (Levens and Enders, 1945)

Red Cells Susceptible

Mumps virus agglutinates fowl cells Beveridge and Lind (1946) found that when the same virus preparation was tested with cells from different fowls, the titers varied from 25–100, the differences in titer were more marked with weak preparations The same workers found that suspensions of human cells gave titers

of 30–50 with a suspension titering 300 with fowl cells, several guinea-pig cell suspensions gave titers comparable to those with fowl cells, pigeon cells were agglutinated to a lower titer than fowl cells.

Technique of Hemagglutinin Titration

Beveridge and Lind (1946) use 0.25 c.c. volumes of virus diluted in twofold steps, with an equal volume of 2 per cent. fowl cells, and finally 0.25 c c. of saline. The tubes are shaken thoroughly, and the tests read when the agglutinated cells have settled to the foot of the tube, at room temperature. The end point is taken as the dilution giving a central button of agglutinated cells surrounded by a thin even zone of agglutinated cells.

Properties of the Hemagglutinin

1. HA is adsorbed by fowl cells, and after 3½ hours at 37° C. is mostly eluted, the red cells are lysed during the elution process (Beveridge and Lind, 1946). Mumps virus does not elute so readily as Newcastle Disease Virus (Burnet, 1945)

2. Human cells treated with mumps virus in allantoic fluid of relatively low titer adsorb virus, subsequently most of the virus can be eluted, leaving relatively unstable cells, after washing, these cells can be stabilized (rendered inagglutinable) by the addition of antiserum (Burnet, 1945, 1946). Such stabilized cells cannot be agglutinated by mumps virus, but are susceptible to agglutination by NDV and influenza virus, cells treated with NDV or influenza viruses are not agglutinated by mumps virus (Burnet, 1945, 1946; Burnet, McCrea, and Stone, 1946). Mumps falls into the same hemagglutinative group as NDV and influenza, and is placed first in the linear series (see Ch LXI).

3. HA is destroyed at 56° C in 20 minutes, but CF activity is not affected (Beveridge and Lind, 1946).

4 The addition of 0.1 per cent formalin causes only a slight fall in titer for up to 7 hours, but a marked drop after 24 hours, amniotic fluid with up to 0 2 per cent. formalin shows no fall in titer after 4 weeks in the refrigerator (Beveridge and Lind, 1946)

5 Untreated amniotic fluid maintains its titer for several days in the refrigerator, but at 37° C there is some fall after 4 hours (Beveridge and Lind, 1946).

6 Etherization reduces the HA titer (Beveridge and Lind, 1946).

7 The bulk of the hemagglutinin and some of the complement fixing antigen are removed by centrifugation at 15,000 r p m. for 1 hour or at 20,000 r p m for 20 minutes, it is probable that the HA is the virus particle itself, and that some of the CF antigen is likewise virus particle, there being also a soluble CF antigen (Beveridge and Lind, 1946, Henle, Henle, and Harris, 1947).

Hemagglutination-Inhibition Tests

Specific antisera inhibit hemagglutination (Levens and Enders, 1945) In these tests, Beveridge and Lind (1946) use 5 times the concentration of virus needed to give the end-point, the virus is formolized. Guinea-pig cells give results easier to read, first, the serum under test (diluted 1/10) must be treated with 10 per cent. packed cells to absorb natural hemagglutinin for guinea-pig cells.

Sera from mumps convalescents may inhibit agglutination to titers of 80–320 (Beveridge and Lind, 1946).

HA-inhibiting antibodies develop in monkey's sera after the inoculation of live (egg) virus, these appear 2 days after complement fixing antibodies and reach their maximum titer 6 days after these antibodies, after 81 days HA-inhibiting antibodies are still present to high titer (Enders *et al*, 1946 *b*) It appears therefore, that the CF and HA antigens are not completely identical

Inhibiting antibodies develop in rabbits after one intravenous injection of virus (Beveridge and Lind, 1946)

Nonspecific Inhibition of Hemagglutination

Normal allantoic fluid, yolk sac and chorio-allantoic suspension, and amniotic fluid from 13–16 day embryos inhibit HA, especially by weak preparations of virus; the inhibiting substance cannot be destroyed in infected material without damaging the agglutinin (Beveridge and Lind, 1946). A similar inhibition is exerted by infected allantoic and amniotic membrane suspensions (Henle, Henle, and Harris, 1947).

Normal rabbit or human serum may inhibit agglutination; heating of human serum at 60° C. for 20 minutes, or rabbit sera at 62° C. for the same time, considerably reduces the nonspecific inhibition titer, without affecting the specific antibody (Beveridge and Lind, 1946). Friedewald, Miller, and Whatley (1947) found that inhibition was produced by normal serum and tissue extracts. Extracts of red cells that are agglutinable by the virus will inhibit agglutination, presumably by competitive combination of the extract with the virus (Bovarnick and de Burgh, 1947, Friedewald, Miller, and Whatley, 1947, de Burgh *et al*, 1947). Cells treated with polysaccharide are not agglutinated (Ginsberg, Goebel, and Horsfall, 1947).

Agglutination of Red Cells by Antiserum

Burnet (1946) found that human red cells treated with potent virus in amniotic fluid could be only partially stabilized, and such cells were agglutinated to high titer by the sera of convalescents. Red cells were prepared by adding 0 2 c.c. of packed washed human cells of group O to 5 c c. of mixed amniotic fluid and saline The tube was placed in a water bath at 37° C for 3 hours, and left overnight in the refrigerator. The cells were then resuspended, centrifuged, and the supernatant discarded. The cells were made up to 2 per cent in saline, and tested at 37° C for stability and agglutinability by a known active serum. Suitable agglutinable suspensions could also be prepared using allantoic fluid, but this proved more difficult The tests were made with 0 5 per cent suspensions of virus-treated cells Doubling dilutions of serum were made in calcium saline and an equal volume (0.25 c c.) of treated cell suspension added. Readings were made after 2 hours in a 37° C incubator by studying the pattern of the deposited cells

Marked antibody rises occurred in convalescence and on active immunization. The titers were higher, but the degree of response was in general similar to that shown by parallel hemagglutination-inhibition tests It seems probable that the agent in mumps virus sensitizing the cells to the agglutinating action of antibody is the virus itself, or an antigenically active derivative thereof.

IMMUNITY REACTIONS

Antigen-Antibody Reactions

The interaction between mumps antibody and antigen can be demonstrated by various techniques

Virus neutralization.

Sera of man, monkeys, and cats neutralize the infectivity of mumps virus on recovery from infection. This neutralizing effect has been demonstrated by inoculating cats with virus-serum mixtures (Wollstein, 1916). Monkeys can also be inoculated with test mixtures (Johnson and Goodpasture, 1934), the parotids can be tested for the quantity of CF antigen produced (Enders *et al*, 1945). Eggs may be inoculated in the allantoic cavity or yolk sac, infection being judged by the presence of CF antigen in the egg fluids when tested with known sera (Habel, 1945 *b*, 1946).

of 30–50 with a suspension titering 300 with fowl cells, several guinea-pig cell suspensions gave titers comparable to those with fowl cells; pigeon cells were agglutinated to a lower titer than fowl cells

Technique of Hemagglutinin Titration

Beveridge and Lind (1946) use 0.25 c.c. volumes of virus diluted in twofold steps, with an equal volume of 2 per cent. fowl cells, and finally 0.25 c.c. of saline. The tubes are shaken thoroughly, and the tests read when the agglutinated cells have settled to the foot of the tube, at room temperature. The end point is taken as the dilution giving a central button of agglutinated cells surrounded by a thin even zone of agglutinated cells.

Properties of the Hemagglutinin

1. HA is adsorbed by fowl cells, and after 3½ hours at 37° C. is mostly eluted, *the red cells are lysed during the elution process (Beveridge and Lind, 1946)* Mumps virus does not elute so readily as Newcastle Disease Virus (Burnet, 1945).

2. Human cells treated with mumps virus in allantoic fluid of relatively low titer adsorb virus, subsequently most of the virus can be eluted, leaving relatively unstable cells, after washing, these cells can be stabilized (rendered inagglutinable) by the addition of antiserum (Burnet, 1945, 1946). Such stabilized cells cannot be agglutinated by mumps virus, but are susceptible to agglutination by NDV and influenza virus, cells treated with NDV or influenza viruses are not agglutinated by mumps virus (Burnet, 1945, 1946, Burnet, McCrea, and Stone, 1946). Mumps falls into the same hemagglutinative group as NDV and influenza, and is placed first in the linear series (see Ch. LXI).

3. HA is destroyed at 56° C in 20 minutes, but CF activity is not affected (Beveridge and Lind, 1946).

4. The addition of 0.1 per cent formalin causes only a slight fall in titer for up to 7 hours, but a marked drop after 24 hours, amniotic fluid with up to 0.2 per cent formalin shows no fall in titer after 4 weeks in the refrigerator (Beveridge and Lind, 1946).

5. Untreated amniotic fluid maintains its titer for several days in the refrigerator, but at 37° C there is some fall after 4 hours (Beveridge and Lind, 1946).

6. Etherization reduces the HA titer (Beveridge and Lind, 1946).

7. The bulk of the hemagglutinin and some of the complement fixing antigen are removed by centrifugation at 15,000 r.p.m. for 1 hour or at 20,000 r.p.m. for 20 minutes, it is probable that the HA is the virus particle itself, and that some of the CF antigen is likewise virus particle, there being also a soluble CF antigen (Beveridge and Lind, 1946, Henle, Henle, and Harris, 1947).

Hemagglutination-Inhibition Tests

Specific antisera inhibit [illegible] ers, 1945) In these tests, Beveridge and Lind [illegible] of virus needed to give the end-point, the vi [illegible] ive results easier to read, first, the serum under test (diluted 1/10) must be treated with 10 per cent packed cells to absorb natural hemagglutinin for guinea-pig cells

Sera from mumps convalescents may inhibit agglutination to titers of 80–320 (Beveridge and Lind, 1946)

HA-inhibiting antibodies develop in monkey's sera after the inoculation of live (egg) virus, these appear 2 days after complement fixing antibodies and reach their maximum titer 6 days after these antibodies, after 81 days HA-inhibiting antibodies are still present to high titer (Enders *et al.*, 1946 *b*). It appears therefore, that the CF and HA antigens are not completely identical.

Inhibiting antibodies develop in rabbits after one intravenous injection of virus (Beveridge and Lind, 1946)

The skin reactions were read at 24 and 48 hours, and the mean value of the measurements in 2 directions recorded

1 Mumps appeared most often in those persons who previously gave a negative skin reaction. Of 89 cases of mumps 75 per cent. occurred in those who exhibited no reaction after 48 hours Of those who reacted, half exhibited a zone of erythema not exceeding 10 mm in diameter

2 Confirmatory of these findings were the results of tests carried out in the first 5 days of an attack of mumps in 13 adults and 27 children, over 90 per cent gave negative skin tests

3 In a number of groups exposed to infection, it was possible to estimate approximately the relationship between the size of the skin reaction and the risk of contracting infection With a negative or weak reaction at 48 hours (diameter 10 mm. or less), the chances were from 1 in 3 to 1 in 6 that the person would develop clinical signs of mumps With a reaction from 11-15 mm in diameter, the chances were 1 in 13, with reactions from 16-25 mm the chances were about 1 50 One may, therefore, regard persons showing a skin reaction of less than 11 mm. as presumably susceptible, and those with a larger lesion as presumably immune

4 It seemed that when the incidence of positive reactors in groups exposed to mumps was less than 50 per cent, secondary cases were fairly numerous When the incidence was over 50 per cent, secondary cases were relatively uncommon

5 Skin tests were carried out in 529 adults and 306 children not known to have had mumps recently There was approximately twice as great an incidence of negative reactors in the children as in the adults There was a lower incidence (63 per cent) of the skin reactors in adults confined in institutions than in students (72 per cent), presumably because of the decreased exposure of the former group The reactions in adults tended to be larger than in children, at 48 hours

6 As the work progressed it became evident that readings taken at 48 hours were the more reliable, reactions proving weak at 24 hours tended to become positive by 48 hours, further, reactions due to the control material were much less commonly seen at the later period

7. On the whole, it appeared that antigen prepared from the monkey parotid was more satisfactory than infected amniotic fluid

8 In 82 per cent of 179 adults giving a history of mumps, the skin reaction at 48 hours was positive (11 mm and over), 9 per cent were negative, and 9 per cent showed reactions under 10 mm Of those giving negative histories, 58 per cent were positive by the skin test, presumably due to subclinical infection

For various reasons, it was not possible to ...
it appeared
adults, there

9 Nearly ... whose serum contained complement fixing antibody could be detected, by the simpler procedure of skin testing, the skin test was more sensitive than the complement fixation test Thus 57 of 111 adults giving a negative fixation test showed positive skin tests It appeared that the accuracy of the skin test in revealing the presumably immune individual was not as great in children as in adults There was a larger proportion of failures to show a positive skin test in those where antibody was present in the serum It is probable that on recovery from an apparent or a subclinical attack of mumps, serum antibody develops before ...

or caused appearanc...
negative skin tests d...
terial was still antig...

11 Observations on small numbers suggested that the intradermal inoculation of antigen might induce resistance to attack

Active Immunity on Recovery from Infection

Experimental.

Cats recovered from infection are resistant to further attack (Wollstein, 1916). Monkeys are also resistant (Johnson and Goodpasture, 1934) Monkeys in contact

Complement fixation.

Complement fixing antigen can be found in the following infected materials

1. It occurs in monkey parotid gland (Enders and Cohen, 1942, Habel, 1945 *b*, 1946, Beveridge, Lind, and Anderson, 1946). It appears within 4 days of infection, and reaches maximum concentration before the development of parotitis (Enders *et al*, 1945).
2. It is found in yolk sac (Levens and Enders, 1945, Habel, 1945 *b*, 1946, Beveridge, Lind, and Anderson, 1946); in amniotic fluid (Levens and Enders, 1945, Habel, 1945 *b*); in the chorio-allantois (Levens and Enders, 1945), and in allantoic fluid (Habel, 1945 *b*; Beveridge, Lind, and Anderson, 1946).

The relatively purified aqueous phase of ether-extracted yolk sac virus contains the same titer of CF antigen as the original, the antigen is preserved by ether or UVL (Habel [illegible]
serum, CF an [illegible]
1946) CF an [illegible]
preserved in the frozen state (Enders *et al.*, 1945).

Antigenic components.

The work of Henle, Henle, and Harris (1947) has shown that complement fixation depends partly on the EB and partly on a soluble antigen

1. In infected eggs, they found complement fixing titers to be higher in membranes than in fluids. There was a discrepancy between complement fixation, infectivity, and hemagglutinating capacity. Both the latter properties were better developed in the fluids.
2. By centrifuging egg fluids for 20,000 r.p m for 20 minutes the infective, hemagglutinating and complement fixing properties were sedimented together with virus particles After centrifuging egg membrane suspensions, however, the supernatant still fixed complement. This soluble antigen was largely removed by further centrifugation at 30,000 r p.m
3. When human convalescent serum was absorbed with virus particle antigen from allantoic fluid, it still fixed complement with the soluble antigen. Absorption of serum with soluble antigen from membrane suspension left antibodies to the virus particle antigen
4. Antibodies against both antigens were found in the sera of children convalescent from mumps. Some sera from individuals giving a long past history of mumps showed antibodies only against the virus particle antigen

Evidently, therefore, one complement fixing component (found especially in egg fluid) is closely linked with the virus The other, found chiefly in membranes, is smaller and soluble

Other reactions.

Antigen-antibody reactions involving the red cell have been discussed above.

Skin Reactivity

Reagents can be prepared from infective materials that elicit a skin reaction in persons who give a previous history of mumps (Enders, 1945). The reagent is prepared from monkey parotid gland and inactivated by heat (Enders, Cohen, and Kane, 1945), or yolk sac antigen can be used (Habel, 1945 *b*).

Reactivity appears 1 week to 3 months after onset, and is unrelated to the development of complement fixing antibodies (Enders, Cohen, and Kane, 1945)

Enders *et al* (1946 *a*) carried out skin tests with a saline suspension of monkey parotid gland inactivated at 65° C for 20 minutes, and preserved with 0 5 per cent. phenol. In some experiments, suspensions of infected amniotic sacs were used

1942; Beveridge, Lind, and Anderson, 1946, Enders *et al*, 1945, 1946 *b*, Habel, 1946). They develop in 10–12 days, reach a maximum at 14, and then decline, some antibody persists for months

In man.

Virus neutralizing antibodies develop in convalescence (Johnson and Goodpasture, 1936 *a*, Enders, 1945, Enders *et al.*, 1945). Antibodies to the particle and soluble antigen may occur separately (Henle, Henle, and Harris, 1947).

Complement fixing antibodies appear in convalescence after about 2 weeks, or if already present, increase in titer (Enders and Cohen, 1942, Enders, Cohen, and Kane, 1945; Beveridge, Lind, and Anderson, 1946) CF antibodies develop after about 2 weeks if virus is inoculated in Stensen's duct, and in about 3 weeks if virus is sprayed (Stokes *et al*, 1946). Complement fixing antibodies develop as a result of subclinical infection (Enders, Cohen, and Kane, 1945).

Maris *et al.* (1946) made a detailed study of the antibody response, using the CFT, with monkey parotid as the antigen: 1. 56/61 cases of parotitis studied appeared in persons giving a negative CFT. Only 1 case occurred among 163 giving positive tests With rare exceptions, a positive CFT indicated resistance.

2. Up to ⅔ of exposed persons in institutions where mumps is occurring may develop a rise in CF antibody from subclinical attack.

They found the CFT positive in 42 per cent. of 386 persons giving no history of mumps. About ⅓ of all infections may be inapparent; inapparent infection occurs in childhood also.

3. The CFT was found to be positive in 77 per cent. of 565 persons giving a history of attack.

4 A titer of over 1/192 was regarded as presumptive evidence of a recent, as opposed to a remote, infection

5. CF antibodies were found in the sera of infants, and the results corresponded with those in the mothers

Serum Antibodies after Vaccination

Experimental.

Virus neutralizing and complement fixing antibodies develop after injection of live or inactivated vaccines and reach a level comparable to those in animals convalescent from infection (Habel, 1946). The presence of complement fixing antibodies does not necessarily mean that the monkey is resistant to infection (Enders *et al*, 1945).

The antibody response is higher when vaccines are incorporated in beeswax oil as an adjuvant (Habel, 1946).

When immune monkeys were challenged with live virus, virus neutralizing antibodies developed to 1/100 or higher within 3 weeks of the challenge—definitely higher than in controls following 1 injection (Habel, 1946). Similar observations have been made with CF and hemagglutination-inhibiting antibodies (Enders *et al*, 1946 *b*).

In man.

Complement fixing antibodies appeared after vaccination with formolized monkey virus in 18/45 cases, 10 days after the first dose. The presence of antibody was usually associated with resistance, but in one resistant group no antibodies were detected (Stokes *et al*, 1946)

After 1 inoculation of infected amniotic fluid, 5/8 persons showed an appreciable rise in agglutination-inhibiting antibody, 4 of those who had a second injection showed no further increase. These 4 persons probably had a basal immunity,

with infected animals may develop resistance, presumably as a result of subclinical infection (Enders *et al.*, 1945).

In man.

Second attacks of mumps are very rare (see Rolleston, 1932). Resistance can be acquired by subclinical attack (Siegel and Camp, 1944), and antibodies develop in a considerable percentage of persons who give no history of mumps (see below).

Active Immunity from Vaccination

Experimental.

Johnson and Goodpasture (1936 *a*) carried out experiments attempting to immunize monkeys with live virus. They were able to induce active immunity by (*a*) causing a clinically evident infection of the parotids; (*b*) producing a subclinical infection, (*c*) spraying virus-containing material into the nose and throat; (*d*) an intracerebral injection.

Inactivated formolized and alum-precipitated formolized suspensions of infected monkey parotid were administered in monkeys by Enders *et al.* (1945). About 60 per cent. of vaccinated animals showed evidence of increased resistance to challenge, as indicated by a complete or partial suppression of the formation of CF antigen in the parotid glands. Later (1946 *b*), monkeys were inoculated with live egg virus, of lowered virulence, by 1 parotid duct. On the 95th day afterward, a challenge of live virus was introduced into the opposite gland The animals developed an accelerated response, with the production of a hard swelling on the 2nd day, which disappeared by the 7th. There was no facial edema This accelerated response appears to be an allergic phenomenon associated with the immune state.

Inactivated virus, prepared by etherization or exposure to UVL of allantoic fluid or yolk sac, given subcutaneously, in many cases protected against parotid swelling when the animals were challenged by the parotid duct (Habel, 1946).

In man.

Various attempts have been made at active immunization in man Levine (1944) sponsored an epidemic in a school, by not excluding contacts once the disease broke out Although about 50 per cent of all susceptible children developed the disease, several associated adults also contracted the infection. Leineberg (1945) recommended the intracutaneous inoculation of defibrinated blood removed in the acute phase

Stokes *et al* (1946) vaccinated children with inactivated formolized monkey parotid virus subcutaneously. They were challenged by the introduction of active monkey virus in Stensen's duct, or by spraying the buccal mucosa. About half the vaccinated children challenged by the parotid duct route developed an accelerated response in the parotids, and this was regarded as evidence of resistance. When the challenge was given by spray, there was no accelerated reaction, but the swellings were less or absent

Enders *et al.* (1946 *b*) sprayed live egg-passed virus of increasing virulence in the mouth at intervals of 8 weeks There was no enlargement of the salivary glands, and CF antibodies developed after use of first passage material.

Serum Antibodies in Recovery from Infection

Experimental.

Bloch (1937–8) could not demonstrate any antiviral action in the serum of monkeys, but Habel (1946) found virus neutralizing antibodies Complement fixing antibodies develop after injection of virus in the parotids (Enders and Cohen,

because in 3 others a rise in antibody was only noted after a second injection (Beveridge and Lind, 1946).

LABORATORY DIAGNOSIS

To obtain specimens of parotid secretion, place swabs over the orifice of the ducts for about an hour, then collect about 3 c.c. of saliva; broth is added to the swabs and saliva. The material is then inoculated in monkeys via the duct, penicillin being added to reduce contamination Yolk sacs can also be inoculated with saliva, using penicillin and sulfonamide, the amniotic cavity is also suitable (Beveridge, Lind, and Anderson, 1946). Leymaster and Ward (1947) recommend the use of saliva mixed with penicillin and streptomycin and inoculated amniotically in 7–8 day embryos.

The main occasions on which laboratory methods may be of help are in the diagnosis of manifestations other than parotitis, particularly those in which no parot[illegible]
may [illegible]
with [illegible]
diagnostic value in any suspected manifestations of mumps. In convalescence, a rise in antibody may enable a retrospective diagnosis to be made (see above)

SERUM PROPHYLAXIS AND THERAPY

A number of authors has used convalescent serum to prevent mumps. Some benefit has been claimed, although it is not as effective as certain other convalescent sera (e g., measles). Regan (1925), for instance, stated that serum (2 to 4 c c.) given before the 7th day after exposure was effective. Zeligs (1932) made a similar observation, also Cambessédès (1933) with larger (10 to 20 c.c.) doses Gunn (1932) did not find the results very satisfactory, but considered a further trial was indicated More recent workers have obtained results that indicate some value (Kutscher, 1940, Lyday, 1941, Wesselhoeft and Walcott, 1942). Hepatitis may follow the use of pooled blood products (Beeson, Chesney, and McFarlan, 1944, McFarlan and Chesney, 1944, McFarlan and Dible, 1944, Neefe, Miller, and Chornock, 1944) The injection of whole blood has been commented on favorably (Hess, 1915, Barenberg and Ostroff, 1931).

Convalescent serum has been given to males with parotitis in an attempt to lower the incidence of orchitis, it has also been used therapeutically The results in either case appear conflicting (Rambar, 1944, 1946, Candel, Wheelock, and Grimaldi, 1945, R. G Smith, 1945) However, gamma globulin prepared from convalescent blood lessened the incidence of orchitis from 24 7 per cent. in controls to 7 8 per cent (Gellis, McGuinness, and Peters, 1945)

CHAPTER XXV

CHICKENPOX (VARICELLA)

CLINICAL FEATURES

Incubation period. This is relatively long, most cases occurring 13 to 17 days after exposure, although 11 to 20 days are the outside limits (Gordon and Meader, 1929).

Prodromal period. The onset of the disease is usually abrupt, although prodromata of vomiting, pyrexia, and erythematous rashes may be noted. Severe hemoglobinuria has been reported in a Jewish child (Kaiser and Bradford, 1929). Lade (1933) has pointed out that cases frequently have a diarrheal stool about a fortnight before the appearance of the rash.

The rash. This is usually the first clinical manifestation of infection, and only a brief description of its characters will be given here (see Rolleston, 1929, Rundle, 1929) Each individual spot of the rash passes rapidly through macular and papular stages to vesicle formation. In certain cases pemphigoid bullae may develop (see Gautier and Thévénot, 1929, Glanzmann, 1936). The vesicles are frequently oval and domed, being situated superficially in the skin; they are generally discretely spaced When the rash occurs on the hands, feet, and scalp the vesicles feel distinctly "shotty," being situated more deeply in these areas The vesicle usually collapses when pricked, with the escape of clear serous, or later slightly turbid, fluid, in certain cases the contents may suppurate. After a few days the lesions begin to heal, the vesicles rupturing spontaneously to form a blood-colored scab In certain cases the vesicle may not collapse entirely, giving an umbilicated scab The separation of deeper scabs may leave white scars which persist for life.

With regard to distribution, the spots are generally noted first, and later most profusely, on the trunk, in contrast to smallpox the extremities are not heavily involved The face is often severely affected and vesicles are usually found on the mucosa of the oral cavity and palate In severe cases stomatitis, laryngitis, and nasal lesions may occur (Millous, 1936). The vesicles usually break out in several crops at intervals of a few days Some days after the onset of the eruption the typical chickenpox patient shows vesicles, scabs, and scars. Associated with the spots there is usually considerable itching General symptoms are slight, a rise of temperature 3 to 4 days after the onset being quite common if the vesicles suppurate

It is well known that various forms of skin irritation serve to localize the distribution of the rash Thus Rivers and Tillett (1923) showed that the rash occurred most profusely under strips of adhesive tape, napkins, soft collars, or on faces affected by acne. Following the intradermal injection of streptococcal toxin the rash was found to be more profuse in that area (Martmer, 1927) Exposure to sunlight or ultraviolet radiation also tends to increase the number of spots in the irradiated area (Mallinckrodt-Haupt, 1934) In one interesting case it was found that the injection of diphtheria prophylactic (TAM) during convalescence resulted in the reappearance of a crop of vesicles on the gluteal, lumbar, and posterior femoral regions (Donald and Brosius, 1931)

Ronaldson and Kelleher (1938) reviewed various anomalous types of rash, illustrated by their own cases They allude, among others, to the following modifications (*a*) abortive rashes proceeding no further than the vesicular or even papular stages, (*b*) rashes retarded in their development in debilitated subjects, (*c*) gangrenous varicella (*vide infra*), (*d*) bullous varicella, (*e*) hemorrhagic varicella, (*f*) varicella herpetiformis

COMPLICATIONS

Although chickenpox is essentially benign, any large series of statistics shows

outbreaks may occur.

1. Surface Complications

The following lesions were those most commonly found by Wishik and Bullowa (1935), over half the total complications being those of the body surface. erysipelas and cellulitis, abscesses, lymphadenitis, and conjunctivitis Gangrene was found in certain cases, especially in the presence of cellulitis This gangrene often involved the superficial abdominal tissues (see also Nichols, 1934, Watson, 1934) Banks and McCartney (1937) recorded a case of gangrenous varicella due to a hemolytic streptococcus, and Lavergne *et al.* (1938) to a *Staphylococcus aureus* The latter also reviewed some 60 papers on gangrenous varicella. True diphtheria bacilli have also been isolated from gangrenous varicella (Warren and Sutton, 1915, Joe, 1918) *Hemorrhages may occur into the vesicles or surrounding skin (see* Tilley and Warin, 1938, Brander, 1940).

2. Other Pyogenic Complications

Otitis media, pharyngitis, laryngitis, tonsillitis, pneumonia, septicemia, appendicitis, and corneal ulcer have all been recorded as complications of varicella (*Mitchell and Fletcher, 1927, Bullowa and Wishik, 1935, Cunningham, 1943*).

mber of later writers (Loewen-

3illo, 1946). Irido-cyclitis may

thritis, myositis, bursitis, and

1927, Ochsenius, 1930, Tilley

1947)

3. Blood Diseases

Various types of blood disease have been reported as complicating varicella Thus, lymphatic leukemia has been recorded (see Goldman, 1930, Holbrook, 1937) Zoster eruptions may also occur in leukemia (see Ch XVI), and it is the *opinion of Philadelphy and Hasslhofer (1934) that* many such eruptions are in reality due to chickenpox.

Purpura may also occur in varicella (Fiessinger, Merklen, and Brouet, 1934, Cohen, 1936, Railliet and Ginsbourg, 1938) Fiessinger's case was one of hemorrhagic aleukemia, Cohen's of thrombocytopenic purpura, and Railliet's one of pronounced anemia.

4. Nervous Complications

mplications is not high (5 out of

cases have been recorded in the

925; Winnicott and Gibbs, 1926,

29, Butler, 1930, Fry, 1932, Gillot,

, 1932, Hallé and Arondel, 1933,

933, Imrie, 1934, Kimura, 1934,

Bernheim, 1935, Zischinsky, 1935, Chavany, 1937, MacIntyre and Beach, 1937, Walcott, 1937, Faust, 1938, Lancaster, 1938, Swyer, 1938). In addition there have appeared a number of general reviews with more or less extensive bibliographies (Fasella, 1929, Cornil and Kissel, 1930, Brain, 1931, Zimmerman and Yannet, 1931;

van Bogaert, 1933, Bergman and Magnusson, 1939, Deal and Gastelu, 1939, Masten, 1940; Waring, Neubuerger, and Geever, 1942, Machado, 1945, Swan, 1946).

The most comprehensive paper is that of Underwood (1935), who has reviewed some 120 published cases He has amplified various existing systems of classification and divided the nervous manifestations into 6 main groups. The clinical picture is variable, and the following are the main features which may be noted· convulsions and meningeal irritation; evidence of encephalitis, myelitis, peripheral neuritis, paralysis of the internal and external eye muscles.

Symptoms of nervous involvement may occur from the prodromal period up to 90 days later, but the great majority of cases develop symptoms between 4 and 10 days after the onset of the illness Lumbar puncture does not usually show any significant departure from normal, although cells may be increased up to about 30 per c.mm.

Underwood's series showed that 80 per cent. of cases recovered, 10 per cent died, and 10 per cent. were left with some permanent sequel, often some muscular paralysis or incoordination

The greatest number of cases of nervous involvement was probably recorded from 1925 to 1932. Many more cases seem to be recognized in France, Belgium, Italy, Germany, and America than in Great Britain.

Pathological features. van Bogaert (1930, 1932) found widespread encephalitis Areas of demyelination were noted, mainly in the centrum ovale, cerebellum, inferior peduncle, and to a lesser extent in the cerebral cortex, even outside these foci there was involvement of the axis cylinders These areas of demyelination were not invariably situated perivascularly. The basal ganglia were diffusely infiltrated with cells, and many ganglion cells in the cerebrum and cerebellum were degenerate.

Zimmerman and Yannet (1931) reported a widespread degeneration of ganglion cells in the brain and cord, in the cells of the cerebral cortex, central gray masses, pontine and medullary nuclei, cerebellum (Purkinje cells), dentate nucleus and both horns of the cord. The vessels of the parietal and occipital lobes were "cuffed" with fat-granule cells, and there was a perivascular zone of demyelination

A case in an adult was examined by Waring, Neubuerger, and Geever (1942); demyelination was present. Swan (1946) found diffuse and perivascular softening in the neostriatum. Perivascular demyelination was found in the white matter.

Etiology of nervous complications Underwood discusses at length the various possible explanations for nervous involvement, such as the coexistence of encephalitis lethargica, the action of an unknown virus, an anaphylactic reaction, but decides that the condition is in all probability due to the development of neurotropic tendencies in the strain of varicella virus itself Many cases of nervous manifestation resemble postvaccinal encephalitis both clinically and pathologically, and the etiology of these 2 conditions must be considered together A full discussion is to be found elsewhere (see Ch. XXXV), here we may state that in our opinion varicella virus is probably one of many agents causing a vascular reaction, characterized by the production of demyelination, in the central nervous system Possibly this reaction is of an allergic nature

5. Congenital Lesions

It is possible that congenital lesions may be attributed to maternal varicella in the first trimester, just as occurs in rubella (Ch. XXIII; Laforet and Lynch, 1947).

CLINICAL PATHOLOGY

The opsonic index (test organisms: *Bact. typhosum*, *Br melitensis*, and *Streptococcus*) was said to be considerably raised in varicella (Piana, 1930).

Although a leukocytosis usually occurs, the blood count is not of very much diagnostic value Mitchell and Fletcher (1927) showed that in infants the count was

often 3,000 cells per c mm above normal from the first day of the illness onward. Between the ages of 6 and 10 a similar increase occurred, but not until the 3rd day, while in adults it did not take place until the 4th to 9th day. These workers noted no significant change in the differential count. Holbrook (1941) refers to a leukopenia at the end of the incubation period. He found an increase in plasma cells early in the eruptive stage

HISTOPATHOLOGY OF THE VARICELLA VESICLE

The histopathology of the vesicle has been described and figured by various authors (see Unna, 1896, Dockerell, 1905; and Tyzzer, 1905–6; Dahl, 1944) and closely resembles that of zoster. The vesicle lies mainly in the prickle cell layer and is dome-shaped, the roof being formed by the stratum corneum and lucidum, and the broad base by the deeper prickle cell layer Although the cavity is subdivided by a few septa, it collapses when pricked The process of vesiculation begins by a reticulating liquefaction in a few prickle cells (Unna). These cavities fuse together to form vesicles which in their expansion compress nonliquefied cells to form septa In addition, ballooning degeneration takes place in the cells at the base, margins, and center of the vesicle These swollen cells, containing numerous nuclei, are usually

vesicle (Manicatide

fibrinous with some

congestion and perivascular multiplication of spindle cells Inclusion bodies have been described by Tyzzer (1905–6). They are eosinophilic or purple granules occurring first in the vascular endothelium and later in the epidermal cells. They are usually intranuclear but intracytoplasmic forms may occur, they measure from 1 μ to 6 μ in diameter.

VISCERAL LESIONS

Giant cells have been described in the tonsils in the prodromal period (Tomlinson, 1939).

Johnson (1940) examined the tissues of a child dying in the acute phase, and found areas of focal degeneration in the esophagus, pancreas, liver, renal pelves, ureters, bladder, and adrenals The cellular changes are like those in the skin. The affected cell is ballooned, and the cytoplasm vacuolated, the nucleus also is rarefied The capillaries associated with the lesions are often destroyed with thrombosis and hemorrhage. Johnson suggests that the virus propagates in the blood, localizes in epithelial cells and multiplies Inflammatory cell infiltration occurs secondarily to infarction and necrosis. Waring, Neubuerger, and Geever (1942) found "virus pneumonia," encephalitis, and toxic nephrosis in an adult

Oppenheimer (1944) examined a case of congenital varicella in a premature infant dying at 11 days. He found disseminated necroses with intranuclear inclusions in skin, esophagus, stomach, intestines, pancreas, lungs, bronchioles, kidneys, liver, adrenals, and thymus.

EPIDEMIOLOGY

Chickenpox is found in all parts of the world. Although the disease is predominantly one of youth, older persons do not escape entirely Thus, while the majority of cases occurs from 2 to 6 years, almost 20 per cent of cases are over 20 years of age (see Mitchell and Fletcher, 1927). The disease has been reported in babies aged 2 to 8 days due to infection *in utero* (Henderson, 1934, Baron, 1935, Shuman, 1939, Oppenheimer, 1944), the oldest case is that of a woman aged 76 (Rolleston, 1932)

In temperate climates the disease is somewhat more prevalent in the 6 winter months than in the summer time, but it does not enjoy any marked seasonal distribution

The disease is one of moderate infectivity and frequently causes difficulty in isolation hospitals, as the condition may smolder in infected wards for a considerable time. When originally introduced to any institution it may be very hard to trace the offender. No child with a frank varicelliform rash may appear to have been admitted, and one must postulate that some entrant had only a few vesicles which were not obvious on clinical examination. Alternatively, a case may have been admitted in the incubation period.

It is probable that varicella is infective from 24 hours before the eruption till at least 7 to 8 days after its appearance. Infection is spread by droplets and droplet nuclei or by contact with the rash. Fomites may play a slight part in the spread of the infection if used directly after being contaminated by the patient. Contacts should be quarantined for 21 to 24 days.

Favorable results, with lowered incidence of infection, have followed irradiation of children's wards and school rooms (Greene, Barenberg, and Greenberg, 1941; Wells, 1945).

Chickenpox in schools. The regulations (*Memorandum*) require cases to be excluded from school for 2 weeks from the appearance of the rash. Contacts need not be excluded (Forbes, 1939).

Chickenpox has been discussed in a special report of the Medical Research Council on epidemics in residential schools (1938). It was found to be the commonest infectious disease in boys and girls, but the attack rate on susceptibles was never a very high one. The epidemics usually lasted throughout the term

ISOLATION OF THE VARICELLA VIRUS

Although it has been suggested that the etiological agent of varicella is a cultivable micrococcus (Auricchio, 1924, Macdonald and Macdonald, 1931), it is generally held that it is a virus.

Human Inoculation Experiments

The infectivity of varicella was first shown conclusively by Steiner in 1875. He was able to reproduce varicellous eruptions by inoculating children with varicella vesicle contents. These observations have been confirmed repeatedly (Kling, 1913, 1915, Lapidus, 1916–18, Meyer, 1918–19, Gyr, 1916–18, Bigger, 1937). In addition other authors have carried out similar experiments, mainly to produce active immunity against the disease, and obtained local lesions (*vide infra*). It should be added that certain workers have failed to transmit the infection with vesicle fluid (Hess and Unger, 1918, Gulácsy, 1933; Wats and Dalal, 1937).

Animal Experiments

A number of workers have failed to transmit the infection to animals, the following having given negative results: monkeys by dermal inoculation (Park, 1902; Tyzzer, 1905–6, Gordon, 1925), guinea-pigs by intradermal injection, after tarring of the skin (Greenthal, 1926), rabbits by corneal inoculation (Salmon, 1905, Tyzzer, 1905–6), or dermal inoculation (Gordon, 1925). However, positive results have been recorded by various workers.

Rabbits. Rivers and Tillett (1923, 1924 *a, b*) injected rabbits with varicella fluid intratesticularly and obtained a definite reaction after a few passages. It soon transpired, however, that they were dealing, not with varicella virus, but with virus III.

Similar experiments were carried out by Taniguchi *et al.* (1932 *a, b*) who injected varicella vesicular fluid intratesticularly into rabbits, thus isolating 3 strains of virus. Taniguchi also injected rabbit passage virus into the anterior chamber of the eye. The cornea and iris became swollen, the aqueous humor turbid, and there was a slight conjunctivitis. Some time earlier it had been shown that eosinophilic inclusions developed in the superficial epithelium after corneal inoculation (Bertarelli, 1909, Swellengrebel, 1911, Gins, 1918), and Taniguchi described clusters of

elementary bodies in corneal endothelial cells. Intradermal injection produced a localized eruption There appears to be every reason for accepting Taniguchi's findings, as it has not been shown that his rabbits were infected with virus III[1]

Monkeys Rivers began to use monkeys, as his particular stock of rabbits was unsuitable for attempting the isolation of virus. He found that vervets (*Cercopithecus lalandi*) and green monkeys (*Cercopithecus sabaeus*) may be used for intratesticular injection (1926, 1927). After such injection large acidophilic granular inclusions form in the nuclei of the tubular cells The monkeys must be young (spermatogenesis must not have begun) and the testicles should be removed after 5 or 6 days

More recently, Eckstein (1933–4) has reported that rhesus monkeys may develop a fatal encephalitis after intracerebral injection of varicella fluid Histologically, thromboses, perivascular infiltrates, and degeneration of the axis cylinders and pyramidal tracts are found. If confirmed, this observation should lead to further progress in the knowledge of the virus and its properties

Morphology

The *elementary bodies* of varicella were probably first described by Aragão in 1911 Since that date they have been studied by a number of independent observers (Paschen, 1917, 1933–4, Taniguchi *et al*, 1932 *a*, *b*, 1934, 1935; Amies, 1933, 1934). The bodies are found in the vesicle fluid in the early stages before crusting begins. They can be purified by differential centrifugation (Amies, 1933), they are specifically *agglutinated by varicella convalescent serum (Amies, 1933), as well as by* zoster convalescent serum (see Ch. XVI). EB's are always smaller and scantier than those of variola (van Rooyen and Illingworth, 1944).

Further proof of the etiological nature of these bodies has been afforded by Taniguchi *et al.* (1932 *a*, *b*) These workers found that the bodies occurred, mainly in clusters intracellularly, in preparations of Descemet's membrane made after intra-ocular injection Also, they could be demonstrated in infected tissue cultures (1932 *a*) and egg membranes (1935). Further, egg membranes in which these bodies could be demonstrated were capable of inducing typical pocks on intradermal injection of children.

EB's have been found by the electron microscope, they are said to measure 210 x *238 mμ (Nagler and Rake, 1938).*

Inclusion bodies, as already mentioned, have been described by various authors (see also Simon and Scott, 1924). These bodies are to be found in the epidermal and vascular endothelial cells of the vesicular lesion, as well as in inoculated rabbits' corneae and monkeys' testes. These large eosinophilic structures are exactly similar to those described in zoster (see Lipschutz, 1921) and are usually found intranuclearly, as they have only been studied morphologically it is uncertain whether or not they represent the etiological agent. Taniguchi *et al*, have also described inclusions, which are intracellular aggregates of elementary bodies and may represent the etiological agent These aggregates have been found in the cells of Descemet's membrane after intra-ocular injection, as well as in the epidermis of the infected chorio-allantois, and tissue cultures.

Cultivation

The virus isolated by Taniguchi *et al.* (1932 *a*) was cultivated in the presence of rabbit lung and testis for at least 11 generations Elementary bodies were demonstrable throughout the passages.

Taniguchi *et al* (1935) used their virus to inoculate eggs and found that pocks

[1] In view of the failure of others to confirm Taniguchi's discovery, it is only fair to add that certain workers feel that his virus may be a strain of variola-vaccinia

developed on the membrane and sometimes on the surface of the embryo as well, elementary bodies could readily be seen in films made from these lesions. The chick membrane attained maximum virulence about the 5th to 6th day after inoculation, when 0 2 c c. of suspension, diluted 10^{10}, was capable of producing local lesions on *intradermal injection of rabbits. Cross* immunity tests failed to demonstrate any antigenic difference between egg virus ("ovo-vaccine") and testicular virus Proof that the agent grown was probably the causal agent of varicella was afforded by showing that after intradermal inoculation of "ovo-vaccine" 13 out of 15 susceptible children developed typical chickenpox vesicles. Teixeria (1936) also noted discrete pocks on the chorio-allantois. However, Irons *et al.* (1941) failed to produce recognizable lesions, and this seems to be the usual experience

IMMUNITY REACTIONS IN CHICKENPOX

(*a*) *Human.* Recovery from varicella is usually associated with a solid immunity to reinfection. It is generally agreed, however, that in a small percentage of cases second attacks do occur. Thus in 775 cases recorded by Mitchell and Fletcher (1927) 9 had had a previous attack (see also Lévy, 1933). Leak (1940) records 4 attacks in a boy aged 13. Relapses may occur, with a fresh eruption, within a short time of onset (Hughes and Smith, 1939).

With regard to the presence of immune bodies in varicella convalescent serum, agglutinins for the elementary bodies have been described (Amies, 1933), complement fixation occurs using varicella crust antigen (Netter and Urbain, 1926), even several years after the attack (Hasskó *et al*, 1938). Finally, serum-virus mixtures fail to produce characteristic inclusions on intratesticular injection of monkeys, presumably due to virus neutralizing antibodies (Rivers, 1926, 1927).

Attempts have been made to immunize children actively by injecting them intradermally, shortly after exposure, with fresh varicella vesicle fluid (Greenthal, 1926, Cherkasoff and Goodeen, 1929, Angarano and Gabrielle, 1931, Csagoly, 1932, Durand and Conseil, 1932). Convalescent whole blood has also been recommended (see Orosz, 1929, Siegl and Rupilius, 1929) It has been stated that the intradermal injection of blood removed during the first 48 hours of the rash prevents a high percentage of contacts contracting varicella (Barberi and Rubini, 1932) Taniguchi *et al* (1935) *have suggested that their "ovo-vaccine" is eminently* suitable for active immunization of children

Some of the above authors have claimed that prophylactic injections have resulted in the development of a modified and milder attack of chickenpox (Cherkasoff and Goodeen), or even checked the spread of an epidemic (Greenthal)

Passive immunization has also been tried, convalescent serum having been used *more or less successfully by various authors (Blackfan, Peterson,* and Conroy, 1923, Weech, 1924, Mitchell and Ravenel, 1925, Gordon and Meader, 1929, see also Lewis, Barenberg, and Grossman, 1937) Other authors, however, have obtained noncommittal or disappointing results (Gunn, 1932, Lewis, Barenberg, and Grossman, 1937)

(*b*) *Animal* The only observation that appears to have been made is that rabbits became immune to intradermal inoculation some 4 to 7 days following a primary intratesticular injection (Taniguchi *et al*, 1932 *a*)

LABORATORY DIAGNOSIS

Tests for the differential diagnosis of chickenpox and smallpox are fully described elsewhere (see Ch XXVII) The obtaining of negative reports from the usual tests is of value in the diagnosis between confluent varicella and variola (Maddock, 1946). As far as chickenpox itself is concerned, films may be made from the vesicles and stained for elementary bodies (see Ch III) An attempt may also be made to isolate the virus by intratesticular injection of rabbits or monkeys

CHAPTER XXVI

VARIOLA-VACCINIA AND ANIMAL POCK VIRUSES

THERE OCCURS in man and animals a number of diseases characterized by the development of pocks, these diseases bear definite resemblances one to another, both clinically and as regards the properties of their causal agents. The diseases which affect man are true smallpox (variola major), alastrim (variola minor), and cowpox. The diseases of animals definitely in this group are cowpox and rabbit-pox. Some workers include also pox diseases of horses, camels, sheep, goat, and swine, but the justification for this grouping is open to doubt By suitable animal passage, the "laboratory" virus of vaccinia can be produced from variola, alastrim, cowpox, and perhaps other sources.

The Origin of the Human and Animal Pock Viruses

Gordon (1925)[1] believes that vaccinia is the more primitive virus partly because it is clearly more comprehensive in its infectivity than variola, also because it is more potent antigenically than variola. Findlay (1936) advanced 2 theories to account for the relationship between the pock viruses First, the animal pock diseases, with variola and alastrim, may have evolved from a hypothetical primitive pox It cannot be postulated, however, in what host, possibly man, possibly animal, this primitive pox occurred. The second possibility is that human variola was the source of the animal diseases and of alastrim In this case man would have been the starting point, and the animal diseases presumably would have originated owing to domestication and contact with him Let us suppose that animals in close contact with man at one time developed an attack of variola It is not unreasonable to suppose that by continued transfer through the particular animal species the variola virus would have become adapted, and have produced a disease of different nature from the original

It does not seem possible, on the evidence available, to support any one of the 3 above-mentioned theories more than the others. The question is, however, largely academic and of no great practical significance.

The Relationship of Variola and Alastrim

The 2 diseases resemble each other closely, apart from the less severe nature of alastrim

The viruses have similar biological properties, but their inclusion bodies can be distinguished They appear to have a similar antigenic structure, as shown by the results of complement fixation, flocculation, and agglutination tests (Kryloff, 1911, Gordon, 1925, Amies, 1932) Cross immunity tests in monkeys have been carried out (Green, 1915–1917, Horgan and Haseeb, 1939) The latter found that immunity was not fully reciprocal, and that the degree of protection induced by alastrim was somewhat greater than that provoked by variola We may conclude that the 2 agents are very closely related, but whether alastrim is a variant of variola, or whether both are derived from a primitive pox is unknown (Ledingham, 1925, Gins, 1927, Kaiser, 1934, Findlay, 1936, Jorge, 1936)

The Relationship of Variola and Vaccinia

By passage through animals, variola virus from the human case can usually be adapted and altered to become vaccinia A similar result can be achieved by variolization or arm-to-arm transfer in man With regard to the nature of the change,

[1] References are appended at the conclusion of Ch XXXV, p 403 et seq

Findlay (1936) suggests that vaccinia is a stable variant of variola (or alastrim) which appears on transfer to a new host The particles of vaccinia are probably present in the original inoculum, and overgrow the variola particles in a selective environment The factors determining the change from variola to vaccinia are imperfectly understood, and under certain conditions variola virus proves stable. For example, variola passed on the chorio-allantois has not been found to develop the properties of vaccinia (Nelson, 1939, 1943; North, 1944).

There are a number of points of distinction between variola and vaccinia viruses For example, the greater infectivity of vaccinia for the calf, rabbit, and other animals, and differences in the inclusion bodies As regards the antigenic structure, there is a close similarity Kolmer (1916) using the CFT found the 2 agents to be closely related. In tests used in the laboratory diagnosis of smallpox, complement fixation is regularly obtained between variola crusts and antivaccinial serum Passive immunity experiments indicate a close antigenic relationship (Pandit *et al*, 1931–2). In cross immunity experiments, usually in monkeys, it has been found that vaccinia protects against variola more effectively than variola protects against vaccinia (Brinckerhoff and Tyzzer, 1906; Bachmann and Biglieri, 1923 *a*, Gordon, 1925, Horgan and Haseeb, 1939). There is little doubt that this is because vaccinia readily proliferates in the skin, and develops a large amount of immunizing material, variola, on the other hand, proliferates less readily. The larger the amount of variola virus in the skin, the greater will be the resistance to vaccinia (see Horgan and Haseeb, 1939) Gordon (1925) regards vaccinia as consisting of equal parts of variolar and vaccinial components Variola as freshly isolated contains only a small amount of vaccinial element, but this increases on passage Horgan and Haseeb (1939) support this view, and suggest that variola contains a group (vaccinial) antigen as well as a highly specific (variolar) antigen The group antigen is r [illegible]
for [illegible]
cor [illegible]
of [illegible]
man against infection by variola, and by the protection that variola confers against vaccinia

The Relationship of Alastrim and Vaccinia

The position is closely analogous to the relationship between variola and vaccinia By animal passage alastrim can be converted into vaccinia. Similar differences exist between the infectivity of alastrim and vaccinia viruses for animals, and the inclusions are not identical The antigenic structure as shown by complement fixation is identical, but the immunizing capacity of the 2 agents varies A number of workers has carried out cross immunity experiments, chiefly in monkeys (Green, 1915–1917), Blaxall, 1923, Gordon, 1925, Sobernheim and Zurukzoglu, 1928; da Cunha and Teixeria, 1934, Horgan and Haseeb, 1939, van Breuseghem, 1940)

These workers have shown that vaccinia immunizes more effectively against alastrim than the reverse This is because alastrim grows less abundantly in the skin than vaccinia It would seem reasonable to conclude that alastrim virus, like variola, consists of a basic vaccinal antigen and a specific alastrimic component.

Apparently certain observers in the Belgian Congo have thought that vaccinia may not protect against the local alastrim in human infections, and it may be that there are unusual local strains, however, the general experience is that *jennerian* vaccination immunizes effectively against alastrim (see Horgan and Haseeb, 1945).

THE NATURE OF COWPOX

Originally brought to prominence by the observations of Jenner, it is now well known that milkers and others may develop pocks on their hands after attending to animals suffering from cowpox The lesions in the human are closely *similar to*

those in the cow, and also resemble those produced by inoculation of vaccine lymph in ordinary vaccination.

Until recently the biological nature of the virus responsible for cowpox in man has been uncertain (Findlay, 1936; Gins, 1938). While some persons have regarded the viruses of cowpox and vaccinia as identical, others have held cowpox to be a virus *sui generis* in the same way as the viruses of classical smallpox and alastrim are so regarded It is probable that the latter view is correct, for Downie (1939 *a*) has shown that there are definite distinguishing features between the viruses of cowpox and vaccinia For instance, the experimental lesions of cowpox are the more hemorrhagic. The vaccinial lesions show a greater tendency to cellular necrosis, and polymorphs are more frequent in the exudate. The inclusions of vaccinia are irregular and granular, while those of cowpox are larger and more homogeneous In cowpox the inclusions are commonly seen in mesodermal cells, while this is less frequent with vaccinia; in cowpox, inclusions may also be seen in the endothelial cells of the small blood vessels. Serological observations also suggest that vaccinia and cowpox are distinct viruses (Davies, Janes, and Downie, 1938, Downie, 1939 *b*). Downie carried out cross absorption tests with EB's, and found that there were *qualitative differences in the heat-labile antigens of cowpox and vaccinia viruses.* Cross protection between cowpox and strains of vaccinia can be shown in rabbit experiments (Horgan and Haseeb, 1945). It is probable therefore that cowpox contains the group antigen found in vaccinia and variola as well as a specific component.

The Relationship of the Animal Pock Diseases

Findlay (1936), in a review of the literature, concluded that some, if not all, of the animal pock diseases mentioned in the first paragraph of this chapter could give rise to virus variants similar to vaccinia The position is, however, obscure and there is scope for considerable further investigation

There is no question that the viruses of cowpox and rabbit-pox (see p. 323) can be fairly regarded as belonging to the variola-vaccinia group. As regards sheep-pox, claims have been made that the causal virus can be converted quite readily into vaccinia (Gins, 1919, Toyoda, 1924, Kii and Kasai, 1926, Kasai, 1931). Rao (1938) using the egg membrane, however, could not produce typical vaccinia. More recently Bennett, Horgan, and Haseeb (1944) have investigated enzootic sheep-pox in the Sudan. They conclude that the causal virus is not related to the variola-vaccinia group. Gins (1919) claimed to have produced a vaccinial variant from goat-pox. Bennett and his coworkers found no immunological relationship between the causal agent and vaccinia, they found that goat-pox and contagious pustular dermatitis viruses shared antigenic components Gins (1927) claimed also to have produced vaccinia from swine-pox

It is evident therefore that later work does not tend to confirm earlier observations on the antigenic character of the causal agents of the pock diseases of some of the domesticated animals It would appear that the virus of ectromelia is closely related to vaccinia (see Ch XXXI)

VACCINIA VIRUS

As has been explained, vaccinia is a purely laboratory virus, of which a number of strains are in existence. It is probable that they have all derived from cases of variola, alastrim, or cowpox Horgan and Haseeb (1945) suggest that vaccinia viruses should be designated by their source, e g, variola-, alastrim-, or cowpox-vaccinia. They carried out cross immunity experiments between various strains of vaccinia, using chiefly dermal scarification in rabbits The strains tested were Khartoum, originally isolated from variola major, LMC (Amies) isolated in London from a case of alastrim, Nigeria, derived from the Lister Institute strain, mouse neurovaccinia (Lagos), neurovaccinia (Levaditi) Irrespective of the origin

of the strains, or animals used for the preparation of the immunizing or test dose, there was full immunological identity of all these strains of vaccinia A similar antigenic structure was found between a stock strain of vaccinia used for lymph production and a vaccinia strain originally deriving from variola (Pandit and Rao, 1940).

There is thus no evidence for the presence of antigenic types of the vaccinia virus. However a number of biological variants have been described (see Ch. XXVIII). Vaccinia has a complex antigenic structure consisting of antigens inherent in the EB, and a soluble (LS) antigen (see Ch. XXXIII).

CHAPTER XXVII

TRUE SMALLPOX, ALASTRIM, AND COWPOX

TRUE SMALLPOX (VARIOLA MAJOR)

In the discrete type, the pocks are few in number and scattered. This type includes cases referred to as "varioloid," often occurring in vaccinated persons, such cases of mild smallpox are capable of infecting nonimmune persons who may develop the severe confluent form of illness.

In the confluent variety the lesions coalesce in such a manner as to leave little or no healthy skin between them.

In those cases which present a combination of appearances the name coherent or semiconfluent smallpox is applied, and where hemorrhage develops the term hemorrhagic smallpox is used

Clinical Features

Nonhemorrhagic smallpox.

The incubation period is usually about 12 days, but may vary from 6 to 22 days in exceptional circumstances. The onset tends to be sudden, the illness being ushered in by pyrexia, headache, vomiting, flushing of the face, congestion of the conjunctivae, and furring of the tongue, with severe backache.

Prodromal rashes are often seen during this initial febrile period about the second day of the illness and, according to the character of the eruption present, have been divided into 3 varieties—erythematous, petechial, or mixed (Ker, 1920).[1] The erythematous form may be scarlatiniform, morbilliform, or multiform in appearance, and may be either general or local in distribution, but is said to avoid *the* face, it is rare in children under the age of 10. The scarlatiniform rash manifests itself as flushing of the skin and is usually distributed evenly over the body surface The morbilliform rash, Ker (1920) states, may closely imitate the rash of measles, with the exception that the macules tend to be larger and are not elevated above *the skin In addition, a multiform type of lesion, with both scarlatiniform* and measly characters, may develop. The petechial rashes are more common than the erythematous varieties, and Rundle (1929) remarked that he had noticed them in about 9 per cent. of his cases. They appear as a collection of punctuate red- or purple-colored spots which develop in the axillary or inguinal region In the latter situation, they may assume a highly characteristic distribution over the lower part of the abdomen, lying within a triangular area bounded above by a transverse line drawn through the umbilicus, laterally by the inguinal ligaments, the pubis being the apex, this condition is referred to by French clinicians as the "bathing drawers rash" (see Fig. 25) Lastly, in the mixed type of rash both the erythematous and petechial forms coexist Prostration is marked in the prodromal period

As the condition progresses, the patient becomes drowsy and restless, and may suffer from delirium and coma On the third day the specific eruption appears, commencing with the formation of small bright red macules, 24 hours *later these* develop into vesicles, which gradually become umbilicated, and increase in size to reach a diameter of 6 mm on the 5th or 6th day. Secondary infection of the vesicles then takes place and they become converted into pustules

The *distribution of the eruption in true smallpox is a characteristic* feature of the malady, and is of considerable diagnostic value. The pocks are most numerous on the face, forearms, wrists, palms of the hands, and soles of the feet, thereby

1 References are appended at the conclusion of Ch XXXV, p 403 et seq

conforming to the so-called centrifugal type of arrangement The lesions are less

detail, drew attention to the possible effect which friction or the intermittent pressure of clothing may exert (see also Wanklyn, 1913)

About the 9th day of the disease healing commences, and the pustular contents undergo absorption The pustules now gradually shrink, becoming converted into

Fig 25 Smallpox eruption as seen on second day of illness, affecting the inguinal region and referred to as the "bathing drawers" eruption At this and the later stage of vesiculation, elementary bodies are readily demonstrable *in tissue scrapings (see van Rooyen and Illingworth, 1944).*

flattened scabs which eventually drop off, to leave behind them an area of superficial discoloration which may disappear completely, if the lesions have not been deep-seated or the papillae damaged On certain parts of the body surface, such as the soles of the feet and palms of the hands, the pustules fail to erupt through the skin, and patches of discoloration remain visible after absorption of the contents Pocks may also form under the nails of the fingers and toes, giving pain

During the pustular stage of the disease, the patient's face becomes greatly swollen and edematous, the nose, cheeks, lips, and ears become thickened, there is difficulty in closing the eyelids and mouth, pus exudes from the conjunctivae, saliva dribbles from the mouth, and an offensive odor emanates from the body. Pocks may also appear on the tongue and larynx, swallowing becomes difficult,

and a painful cough may develop. These lesions are accompanied by severe constitutional symptoms, and drowsiness, delirium, and coma may become pronounced (see Fig. 26).

The temperature chart in a case of smallpox shows 2 rises; the first or pre-eruptive falls with the appearance of the rash, and the second, due to secondary pyogenic infection developing at the pustular stage, about the 8th or 9th day. The height of the fever ranges from 103° to 105° F., according to the severity of the case, and is accompanied by an increase in the pulse rate to about 120 beats per minute.

Infection of the fetus *in utero* may occur (Horning, 1932).

We do not intend to discuss the differential diagnosis of smallpox on clinical grounds, but would draw attention to the cardinal features of prodromal rashes

Fig. 26. Smallpox pustular eruption

and prostration, the 2 rises of temperature, and the centrifugal distribution of the rash. The presence of a recent successful vaccination renders a diagnosis of smallpox unlikely.

Hemorrhagic or toxic smallpox.

This variety is the severest form of the malady and is attended by the highest mortality. Curshmann (1875) has divided the condition into 2 types, the first named "purpura variolosa," also known as true hemorrhagic or black smallpox, and the second, which he has called "variola hemorrhagica pustulosa," is also referred to as vesicular hemorrhagic smallpox Ricketts and Byles (1908), however, pointed out that these 2 forms of toxic smallpox were not sharply differentiated

True hemorrhagic or black smallpox. This may commence with a prodromal rash, bright red in color. It may be accompanied by a high temperature and numerous hemorrhages into the skin of the groins, axillae, face, and other regions. Bleeding may also occur from any part of the body which is capable of hemorrhage (Ker, 1920) Death often occurs about the 3rd day before the true eruption has

had time to appear, but when it occurs on the 5th day, an early eruption may be evident.

"*Variola hemorrhagica pustulosa*" *or vesicular hemorrhagic smallpox.* The condition begins with high fever and may be preceded by a prodromal rash. Hemorrhages into the skin are a marked feature of the disease, and these may occur either before or after the appearance of the vesicular stage of the true eruption. The constitutional disturbance is usually very severe and the patient seldom lives long enough to reach the pustular stage.

Wilkinson (1943) in a full account of toxic smallpox in Asia, draws attention to the prostration, mental clearness, fetor, enlarged liver, rising respiration rate, and poorly developed focal lesions He found the "lobster" prodromal erythema to be followed invariably by a fatal course

Mortality

The death rate from smallpox varies according to the clinical severity of the disease. One of the most important papers dealing with the influence of the severity of the disease on mortality is that of Sweitzer and Ikeda'(1927). During the course of an epidemic of smallpox at Minneapolis, in 1924–5, affecting 581 persons, these authors reported the following death rates in the different clinical varieties observed Among 225 cases of the discrete type 14 died, so that the death rate was 6 *per cent. Among 151* confluent cases, 68 deaths occurred, the rate being accordingly 45 per cent Among 144 cases of the hemorrhagic type, 113 died, the mortality rate thus being 78 per cent. Purpuric smallpox (variola purpurica) was invariably fatal

The above figures offer a striking contrast between the death rates from the different forms of variola major, and alastrim, in which the disease is almost never a cause of death by itself (see Hay, 1938).

Clinical Pathology

The urine is diminished in volume and the specific gravity is high, it contains deposits of uric acid and urates, and occasionally albumin or sugar may be present The excretion of chlorides is reduced and sulfates increased, blood, when found, is regarded as a bad prognostic sign.

Blood changes. According to Magrath, Brinckerhoff, and Bancroft (1904), alterations occur in the total and relative numbers of the white blood corpuscles during an attack of smallpox. At the end of the incubation period lymphocytosis develops. This is followed by an absolute leukopenia at the time of onset of symptoms At the stage of pustulation when secondary pyogenic invasion occurs, polymorph leukocytosis takes place Other workers who have made observations on the blood changes are Ferguson (1902), Erlenmeyer and Jalkowski (1913), Schilling (1916), Simon (1918), and Hinojar and Corvacho (1940).

The blood changes in hemorrhagic smallpox have been investigated by Ikeda (1925) and Easton (1945) There is a moderate leukocytosis involving granulocytes or lymphocytes, a marked and progressive thrombopenia develops, accompanied by the appearance of polychromasia, punctate basophilia, and normoblast cells. Myelocytes, metamyelocytes, Turck cells, and neutrophil leukocytes showing nuclear degeneration are also found, but the erythrocyte count and hemoglobin percentage remain normal.

Inflammatory Complications of Smallpox

In cases exhibiting severe secondary infection of the skin, boils, abscesses, carbuncles, erysipelas, or permanent loss of hair may result. Eye lesions, such as keratitis, iridocyclitis, and hypopyon ulcers may occur. Smallpox is one of the commonest causes of blindness in India (Sen, 1945). Otitis media, osteomyelitis, cystitis, orchitis, and oophoritis have also been observed

Nervous Complications

Cases of smallpox complicated by involvement of the central nervous system have been reported by numerous workers (Leroy d'Etiolles, 1856, Gubler, 1860, Bernhardt, 1871; Gubler and Laborde, 1871; Roger and Damaschino, 1871; Westphal, 1872, 1874; Wohlrab, 1872, Whipham and Myers, 1886; Combemale, 1892; Spiller, 1903; Aldrich, 1904; Kleineberger, 1913, Wilson and Ford, 1927; *Report*, 1930, Troup and Hurst, 1930, Marsden and Hurst, 1932; Brouwer, de Jongh, and Rochat, *1933, Rice and Carey, 1933, Marsden, 1934). The literature of the subject* has been reviewed by various writers (in particular Aldrich, Turnbull and McIntosh, 1926, Wilson and Ford, Marsden and Hurst).

These complications are rare, and usually develop 5 to 13 days after the appearance of the focal rash, various clinical features may occur, such as encephalitis, speech disorders, delirium, meningitis, spinal symptoms, and peripheral neuritis.

The histopathology has been described by various recent workers who have found that it is, as a general rule, indistinguishable from that of postvaccinal encephalitis (see Ch. XXXV)—demyelination and perivascular infiltrations being characteristic (Wilson and Ford, 1927; *Report*, 1930, Troup and Hurst, 1930, Marsden and Hurst, 1932).

Pathology of Variola Major

The skin.

The appearances presented depend, of course, on the stage of the disease at which the patient dies, but this usually occurs from the 10th to the 13th day, at which time the skin eruption has reached the pustular stage. The pocks are mostly superficially situated

The histology of the smallpox skin lesion has been described in great detail by Michelson and Ikeda (1927), who found that the earliest signs of infection are slight edema of the papillary body, and plasma cell infiltration around the capillaries and blood vessels of the affected site, accompanied by small hemorrhages at the tips of the papillae. Other changes are perivascular lymphocytic infiltration, separation of the deepest epithelial cells, and the formation of areas of "ballooning" and reticular degeneration in the more superficial epithelium

As the condition proceeds, a clear serous exudate develops, which fills the spaces formed within the degenerated epithelial layer so that gradually a vesicle, consisting of an accumulation of fluid inside a number of spaces formed by strands of reticulum, results In its structure, therefore, the vesicle is a multiloculated lesion which cannot be collap ... , the vesicle fluid becomes infected with ... as staphylococci, pneumococci, or hemo ... 922) This is followed by polymorphonuclear leukocytic infiltration, the formation of pus, rupture of the reticulum strands, and the development of an umbilicated pustule.

Councilman, Magrath, and Brinckerhoff (1904) state that these changes may either occur wholly within the epidermis, the fluid contents of the pock being separated from the corium by a layer of comparatively intact cells, or the corium may constitute the bottom of the pustule, in which case there is usually necrosis of the papillary border

Varying degrees of hemorrhage may accompany the changes already mentioned, thus, Ikeda *(1925)* and Michelson and Ikeda *(1927)* have distinguished 3 varieties of the hemorrhagic form of the disease according to the histological changes present, which are as follows

1. The hemorrhagic pustular form, this is characterized clinically by the presence of hemorrhages in or under fully developed pustules.

2. The primary purpuric type, this appears clinically as an intense cherry-colored erysipeloid exanthem showing marked subcuticular and submucous ex-

travasations of blood, histologically, there are no variolous changes in the epithelium overlying the purpuric spaces

3 This variety has been named the secondary purpuric form. Clinically it includes those cases which develop purpuric signs after the development of the pocks, the principal histological features are typical vesicular and pustular lesions of the epidermis accompanied by hemorrhages into the corium, as in the case of the primary type.

Elementary bodies are present in the vesicle fluid during the early stage of the disease The inclusion bodies occur within the cytoplasm of epithelial cells, they are usually acidophilic, and surrounded by an unstained halo.

Healing of the pock is brought about by absorption of the fluid, and superficial necrotic changes, eventually a crust develops consisting of a mass of degenerated epithelial cells, leukocytes, and debris enclosed between two layers of horny epidermis. The crust is eventually cast off.

The respiratory system.

The mucous membrane of the palate, fauces, pharynx, larynx, and trachea is swollen and edematous, and may present numerous discrete nodular elevations (or pocks), with areas of necrosis and submucous hemorrhage (see Ponfick, 1872, Eppinger, 1876, Breynaert, 1881, Huguenin, 1897, Roger, 1902, and Perkins and Pay, 1903)

In severe cases the lungs may be edematous, swollen, and hemorrhagic, with *patches of atelectasis, areas of bronchopneumonic consolidation, and occasionally* gangrene. Gelatinous pleurisy and hypostatic pneumonia have been described in cases of purpuric smallpox by Sorensen and Sorensen (1925). Desquamation of bronchial epithelium with hemorrhages into the peribronchial tissues was observed by Ikeda (1928), Keysselitz and Mayer (1909) found Guarnieri bodies in alveolar cells.

Other systems.

Alimentary tract. The lesions are similar to those described in other organs, e g, hemorrhages with edema, and may occur in the esophagus, the lining of the stomach, and the intestines.

Liver. Cloudy swelling, fatty degeneration, and marked hemorrhages beneath the capsule and into the parenchyma have been described (see Roger, 1902, Keysselitz and Mayer, 1909, Ikeda, 1928, and Lillie, 1930)

Kidneys Cloudy swelling, degeneration of the convoluted tubules, petechial [illegible]

[illegible]

absence of polymorphonuclear leukocytes, decrease in the number of myelocytes, and dilatation of the rib marrow

Spleen This is usually normal but may show septic infarcts

Heart This structure shows cloudy swelling of the myocardium with punctate hemorrhages into the epicardium Bacterial endocarditis may be found if secondary *infection has been responsible for death*

Thymus Multiple focal hemorrhages and necroses are present The reticulum [illegible] and replaced

[illegible] ltrations have [illegible] ation by Per-[illegible]

Other organs. The testicles and ovaries may show small lesions (Béraud, 1859, Chiari, 1886, 1889) Similar changes may be evident in the epididymis and prostate.

The brain appears congested, and the blood vessels of the pia mater are injected The placenta shows areas of degeneration and polymorphonuclear infiltration.

ALASTRIM

This disease is also known as variola minor, amaas, kaffir-pox or milk-pox

Clinical Features

After an incubation period of 10 to 15 days, the disease is ushered in with a sudden rise of temperature to 103° to 104° F. or higher, accompanied by headache, backache, pains in the limbs, vomiting, furring of the tongue, and constipation. On the 2nd to the 5th day of the patient's illness a rash develops, and at the same time the constitutional symptoms abate in severity, while the temperature falls (McSweeney, 1930–1). Vesicles next develop, and simultaneously there may be a feeling of tension beneath the skin, but the severe constitutional upset, mental depression, and the characteristic odor of the skin often observed at the corresponding stage during an attack of variola major are absent in alastrim

The eruption does not appear in crops, but takes at least 3 days to develop. It begins on the face, forehead, dorsum of the wrists and the forearms, and in severe cases the whole body may become covered. The scalp, mouth, hard and soft palate, the cheeks, trachea, larynx, palms of the hands, soles of the feet, and genitalia are usually involved to a lesser extent; the neck, upper part of the trunk and abdomen, the inner side of the thigh, and the circumorbital area may escape attack (Moody, 1922). McSweeney (1930–1) states that in general, the lesions tend to be centrifugal in their disposition, and when present on the trunk, more pocks are found on the back than on the chest and abdomen (see also Rudolph, 1911). They also show a tendency to avoid the midline of the body and the axillary spaces. The lesions begin as a series of papules which 36 hours later turn into vesicles, measuring 4 to 5 mm in diameter, they are either dome-shaped or flat-topped with a dark-colored central area, and are filled with a clear exudate. On the 3rd day of the illness, this clear vesicular fluid becomes invaded by polymorphonuclear leukocytes, followed by infection with pyogenic organisms on the 6th day, after which a second slight rise of temperature may occur At this stage the skin lesion is a pustule, and is surrounded by a red areolar margin with an area of induration and subcutaneous swelling, so that, to the touch, it seems tense, hard, and shotty. Primary umbilication is absent, and on the 8th to 9th day absorption of the fluid occurs and secondary umbilication develops.

At this stage of the illness the skin lesions may either be delicate and closely set, or else coarse and discrete, alternatively, they may be confluent and hemorrhagic. On the 12th day, in a mild case of alastrim, convalescence is well advanced and desquamation should be completed by the 21st day. Elementary bodies occur in large numbers within the pock material Inclusions can be found in the epithelial cells

Occasionally the differential diagnosis of alastrim and variola major may present difficulties, and some of these have been referred to by Pierce (1935), van Campenhout (1935) Marsden (1936) and Hay (1938) give full accounts of the clinical features.

Complications

Bronchopneumonia is the most serious complication, and when lesions develop on the surfaces of the respiratory passages, septic material tends to accumulate and obstruct breathing Impetigo, boils, and eczema are other sequelae.

Pathology

If death occurs, it usually takes place after about 10 to 12 days, the most fatal cases being those with confluent or hemorrhagic rashes.

The skin.

We shall limit our description of the histology of alastrim to quoting the work of Torres (1935–6), who has devoted a considerable amount of study to this matter. The following description is based, he states, partly on human biopsy tissue and partly on material obtained from infected monkeys There are 4 main stages in the development of the alastrim lesion (*a*) proliferation, (*b*) vesiculation, (*c*) pustulation, and (*d*) desquamation

(*a*) *Proliferation* The epidermis is thickened, and cellular proliferation occurs both upward and downward as a definite hypercanthosis; mitoses are not conspicuous Numerous malpighian cells contain the characteristic alastrim basophilic intracytoplasmic bodies (see p. 340) The nuclei of malpighian cells are swollen, and contain small vacuoles. There is marked inflammatory change in the papillary bodies, and the corium below the hypertrophied epidermis is found to be compressed The papillary eminences are narrowed and obliterated. The papillary lymph vessels are dilated, and vessels are surrounded by numbers of polymorphs and endothelial cells Torres stresses this change as supporting the view that the primary reaction in alastrim is a vascular change in the dermis, an initial anemia being followed by hyperemia and edema Later there occurs degeneration in the malpighian cells.

(*b*) *Vesiculation* In this stage multilocular vesicles form, each vesicle occurs in the top of the hypertrophied malpighian layer. Compared with variola major, "balloon" degeneration is rather scarce, but is found also in the upper layers of the stratum germinativum, associated with reticulating reaction This reticulating degeneration is the main change in the vesicles of alastrim, and is evidenced by the formation of minute vacuoles in the cytoplasm of many of the malpighian cells, which eventually become confluent with the formation of a multilocular vesicle The malpighian cells of the bottom and sides of the vesicle are quite normal in appearance, in variola, however, these cells show "balloon" degeneration or necrosis The most typical feature is the presence of giant epithelial cells at the bottom and sides of the vesicle, they may also occur in the middle layer of the hypertrophied epidermis The vesicle is roofed by the horny layer and compressed superficial cells of the stratum germinativum

(*c*) *Pustulation.* Polymorphs begin to accumulate during the stage of vesiculation, but there is no abrupt onset of the stage of pustulation When the pustule is well advanced the vesicle is packed with polymorphs, there is much necrosis of the malpighian cells

Inflammatory changes are marked in the cutis in both the vesicular and pustular stages Cytoplasmic inclusions are regularly found in malpighian cells at the bottom and sides of the vesicle In human beings intranuclear bodies are very rare.

(*d*) *Desquamation.* The lesion heals by the formation of a crust composed of devitalized cells and degenerate polymorphs, this crust is eventually separated by the ingrowth of epithelium from the sides

Other organs.

The respiratory passages may contain septic and necrotic material, and pocks may be evident throughout the entire length of the trachea The lungs may show evidence of hemorrhagic bronchopneumonia. Other changes observed are fatty degeneration with hemorrhages into the kidney, hemorrhages into the epicardium at the root of the aorta, the walls of the le[illegible]

The stomach contains altered blood, [illegible]
its mucous membrane The intestines ar[illegible]
may be occluded with necrotic debris, [illegible]
being the principal portions affected The mucous membrane lining the bladder shows similar changes The liver shows fatty degeneration, but the spleen usually appears unaffected (see Moody, 1922).

The brain appears congested, and the blood vessels of the pia mater are injected. The placenta shows areas of degeneration and polymorphonuclear infiltration.

ALASTRIM

This disease is also known as variola minor, amaas, kaffir-pox or milk-pox.

Clinical Features

After an incubation period of 10 to 15 days, the disease is ushered in with a sudden rise of temperature to 103° to 104° F. or higher, accompanied by headache, backache, pains in the limbs, vomiting, furring of the tongue, and constipation. On the 2nd to the 5th day of the patient's illness a rash develops, and at the same time the constitutional symptoms abate in severity, while the temperature falls (McSweeney, 1930–1). Vesicles next develop, and simultaneously there may be a feeling of tension beneath the skin, but the severe constitutional upset, mental depression, and the characteristic odor of the skin often observed at the corresponding stage during an attack of variola major are absent in alastrim.

The eruption does not appear in crops, but takes at least 3 days to develop It begins on the face, forehead, dorsum of the wrists and the forearms, and in severe cases the whole body may become covered. The scalp, mouth, hard and soft palate, the cheeks, trachea, larynx, palms of the hands, soles of the feet, and genitalia are usually involved to a lesser extent, the neck, upper part of the trunk and abdomen, the inner side of the thigh, and the circumorbital area may escape attack (Moody, 1922). McSweeney (1930–1) states that in general, the lesions tend to be centrifugal in their disposition, and when present on the trunk, more pocks are found on the back than on the chest and abdomen (see also Rudolph, 1911). They also show a tendency to avoid the midline of the body and the axillary spaces. The lesions begin as a series of papules which 36 hours later turn into vesicles, measuring 4 to 5 mm in diameter, they are either dome-shaped or flat-topped with a dark-colored central area, and are filled with a clear exudate. On the 3rd day of the illness, this clear vesicular fluid becomes invaded by polymorphonuclear leukocytes, followed by infection with pyogenic organisms on the 6th day, after which a second slight rise of temperature may occur. At this stage the skin lesion is a pustule, and is surrounded by a red areolar margin with an area of induration and subcutaneous swelling, so that, to the touch, it seems tense, hard, and shotty. Primary umbilication is absent, and on the 8th to 9th day absorption of the fluid occurs and secondary umbilication develops

At this stage of the illness the skin lesions may either be delicate and closely set, or else coarse and discrete, alternatively, they may be confluent and hemorrhagic On the 12th day, in a mild case of alastrim, convalescence is well advanced and desquamation should be completed by the 21st day. Elementary bodies occur in large numbers within the pock material Inclusions can be found in the epithelial cells

Occasionally the differential diagnosis of alastrim and variola major may present difficulties, and some of these have been referred to by Pierce (1935), van Campenhout (1935) Marsden (1936) and Hay (1938) give full accounts of the clinical features

Complications

Bronchopneumonia is the most serious complication, and when lesions develop on the surfaces of the respiratory passages, septic material tends to accumulate and obstruct breathing Impetigo, boils, and eczema are other sequelae

Pathology

If death occurs, it usually takes place after about 10 to 12 days, the most fatal cases being those with confluent or hemorrhagic rashes.

LABORATORY DIAGNOSIS OF SMALLPOX

Laboratory diagnosis is of the greatest assistance in confirming the clinical diagnosis, particularly in the initial cases of an epidemic. Laboratory methods may prove of value in cases doubtful on clinical grounds. The diagnostic methods have improved very considerably of recent years, and full accounts based on extensive personal experience have been given by Downie (1946, 1947) and van Rooyen (1946).

Collection of Specimens, and Selection of Test

van Rooyen (1946) recommends the following procedures, the actual technique of the tests being described later (Table 11 summarizes the recommendations) It should be remembered that a retrospective diagnosis may be made in cases where laboratory examinations are not immediately available, for variola virus survives in crusts in the refrigerator, or even at room temperature for over a year (North, Broben, and Mengoni, 1944, Downie and Dumbell, 1947 *a*, *b*)

Day I Initial febrile stage prior to rash

There is no laboratory procedure which will provide useful information

Days II and III Bathing-drawers rash and maculopapular eruption

If the groins and buttocks show an early petechial rash, the diagnosis can be confirmed beyond doubt in less than half an hour by examining lesions for the presence of elementary bodies The specimen is collected thus A sterile sharp-pointed scalpel and three well-cleaned glass microscopic slides are required, with a bottle of ether and absolute alcohol Choose a dozen typical petechiae, clean them with cotton wool soaked in ether, scrape the red central base of each lesion with the point of the knife, and rub the exudate with a circular rotary motion over the surface of the slide Four smears are made on each slide. Thereafter the preparations are allowed to dry in air for 10 minutes, treated with sterile physiological (0 86 per cent) saline for 3 minutes, placed upright in a rack, allowed to dry, flooded with a mixture of equal volumes of alcohol and ether for 3 minutes, the mixture is poured off, the slides are dried in air, wrapped in clean paper and sent to the laboratory with the request that they be stained by Paschen's method, and examined for presence of variola-vaccinia elementary bodies The bacteriologist should be able to provide a reply within 30 minutes after receipt of the specimen. If virus bodies are found, the case may safely be regarded as variola, but if no elementary bodies are visible, scrapings should be repeated every 4 hours

Paul's test provides a method of isolating virus, and if the result is positive the diag-

ts, but

Days IV and V Vesiculation

goc

cap

the complement fixation or flocculation reactions Both procedures occupy about 12-24 hours, and are highly specific for the variola-vaccinia group

Days VI to VIII Pustulation

Pustulation is generally pronounced at this stage, and the introduction of streptococci, staphylococci, *B coli*, and other secondary contaminating organisms makes it difficult to carry out the direct film technique By carefully selecting lesions containing clear fluid, scraping the red periphery of individual pocks, and by avoiding the presence of serosanguineous pus, it is occasionally possible to obtain reasonably satisfactory preparations showing elementary bodies Paul's test can be carried out, or virus recovered by intratesticular inoculation of rabbits with pustule contents Antiseptics must be used to suppress the growth of bacteria and cocci Penicillin must also be used when inoculating eggs

Serological tests offer the best prospect of arriving at a laboratory diagnosis after the

SMALLPOX MODIFIED BY IMMUNITY

Variola major and minor may occur in modified form in persons protected by vaccination. The patients usually have little or no constitutional upset or perhaps a mild influenzal type of illness. There may be headache, fever, and prostration There are seldom over a dozen focal lesions, and these are often on the wrists, forehead, and backs of the hands. Of recent years many such cases have been noted, and they have often given rise to outbreaks of unmodified smallpox (D'Arcy, Moore, and Whetter, 1943; Beaumont, 1946, Conybeare, 1946).

As lately restated by Wilkinson (1942) smallpox may be modified by vaccination in various ways (1) The toxic phase is attenuated. (2) The total number of skin lesions is lessened. (3) The natural maturation of these lesions is shortened These 3 effects disappear, as immunity resulting from vaccination wanes, at different rates. First to be lost is the toxemia-modifying property, then the property of modifying the number of lesions, and lastly the property of altering maturation. Accordingly, toxic smallpox not uncommonly kills those with good vaccination scars. In others, a severe toxic phase may be followed by a focal phase of a few lesions only.

It is probable that modified smallpox may very rarely occur in persons showing some natural immunity, or associated with the invasion of a strain of virus of modified virulence.

It may be difficult to make the diagnosis between varicella and modified variola, but the following points are helpful (League of Nations, 1940) (1) In varicella the rash may precede the fever or appear with it. (2) The varicella lesions are more superficial. (3) The maturation is more rapid in varicella, and crops occur at all stages (4) In varicella the distribution of the lesions favors the less exposed parts

Contacts of smallpox, particularly those protected by vaccination, may develop a febrile illness without rash, and this has been known as "contact fever," abortive smallpox, or variola sine variolis (Conybeare, 1939, 1946, Bowe, 1942; Napier and Insh, 1942, Easton, 1945, Boul and Corfield, 1946). This type of illness may be a cause of confusion in the diagnosis of smallpox, for example in reception houses, and in many cases it is probable that the symptoms are due to a recent vaccination and not to variola, or alternatively are nonspecific (Tyrrell, 1942) The symptoms, those of a toxemia, include headache, fever, backache, malaise, shivering, and catarrh, but rapidly clear up Howat and Arnott (1944) described fine diffuse mottling in x-ray pictures of the lungs, presumably due to a virus pneumonia

SPECIFIC TREATMENT OF SMALLPOX

Sulfonamides have been widely used, particularly in variola major (Hinojar and Corvacho, 1940, Patel and Naidu, 1940, Couzi and Kircher, 1941, Vengsarkar, Poonen, and Walavalkar, 1942, Wilkinson, 1942, Rao and Natarajan, 1943, Cottrell and Knights, 1943, Leishman, 1944, Sen Gupta, 1944, Vengsarkar and Rangnekar, 1944, Easton, 1945, Osborne, 1945) The majority has recorded definite benefit in the following respects, especially with sulfathiazole administered early in the disease, the pustular stage is less pronounced, secondary invasion of the pocks is less marked, and secondary fever may be abolished, complications are less frequent; convalescence is shortened, and mortality is reduced Toxemia is not affected.

Convalescent serum, from recently vaccinated persons or smallpox convalescents, has been used, and it has been claimed that the course is shortened and the pustular stage aborted (Couzi and Kircher, 1941, Panja and Das, 1942, Wilkinson, 1943)

Antibiotics Some favorable reports on the use of penicillin have appeared (Jeans, Jeffrey, and Gunders, 1944, Foulis, 1945, Weeks and McClelland, 1947)

pustules be collected on glass slides, and allowed to dry. On reception in the laboratory, the exudate was dissolved in saline and applied to the scarified cornea of a rabbit. The animal was killed after 48 to 72 hours, the eye removed and placed in corrosive sublimate Examination with a hand lens showed the presence of raised white papular opacities in positive cases It should be noted that many years earlier, Guarnieri (1892) and Huckel (1898) had shown that lesions developed on the rabbit's cornea after inoculation with the contents of smallpox vesicles, to Paul, however, goes the credit for introducing this reaction as a diagnostic test. The value of Paul's test has been confirmed by various authors (Gins, 1916 *a*, *b*, 1930 *a*, Gasteiger and Niederwieser, 1931–2, Jadassohn *et al*, 1931; Torres, 1935–6, Torres and Teixeria, 1938)

We shall now describe in some detail the method of applying Paul's test as recommended by Scott and Simon (1923).

Collection of material. The vesicles or pustules are wiped over with alcohol, and then incised with a sterile lancet. The contents are collected on slides, and sent to the laboratory. Scabs or crusts may also be used

The test proper. The rabbit's corneae are scarified with a dissecting needle, the material on the slide is emulsified in saline, and transferred to the corneae on a coverslip or platinum loop. After 48 hours, the corneae are examined with a hand lens, and in positive cases tiny lesions like air bubbles are seen, perhaps with depressed centers The rabbit is then killed and the eyes placed in a sublimate bath (2 volumes of a saturated solution of mercuric chloride, and 1 volume of 96 per cent alcohol). After 2 to 4 minutes the eyes are transferred to 70 per cent alcohol Examination should then be carried out with a lens, against a black background. In positive cases the background of the cornea appears white, but there are a number of intensely white opaque elevations, sometimes with a central crater, these lesions vary in number from 3 to 24, and although usually discrete, may be confluent.

Rapid histological examination This is carried out as follows

(*a*) Place the whole eye in sublimate, and then in 70 per cent. alcohol.
(*b*) Then place in sublimate again for 10 minutes
(*c*) Excise the cornea and place in absolute alcohol for 1 minute
(*d*) Place the cornea in each of the following for 1 minute iodized alcohol, absolute alcohol, equal parts of alcohol and chloroform, chloroform, saturated solution of hard paraffin in chloroform at 40° C, liquefied hard paraffin at 60° C.
(*e*) The cornea is then embedded, and sagittal sections are cut.

Microscopical examination of the cornea Microscopically, there is to be seen a number of epithelial hummocks, at first, these elevations are due to a swelling of the basal epithelial cells which throws the superficial cells out of their normal alinement The epithelial layer appears twice as broad as usual The changes are most pronounced in the center of the elevation, where necrosis occurs Guarnieri bodies can be found in the lesions

Paul's test in alastrim Torres (1935–6) reported as follows on the result of Paul's test in alastrim When placed in the sublimate bath, in certain cases tiny yellowish-gray elevations can be seen along the lines of scarification. In other cases the only naked-eye change is a uniform thickening along some of the scarifications In th[illegible]
cen[illegible]

as i[illegible]
rest[illegible]

Downie (1946) has not found the test reliable in Britain in cases of variola major.

5th day of disease As much pustular exudate as procurable should be gathered into glass capillary tubes, sealed with a flame and sent to the laboratory.

Days IX to XIV: Desiccation and desquamation.

During the process of drying of the pustules followed by desquamation, serological tests are the quickest method of securing laboratory evidence of infection. They are suitable in missed cases of smallpox seen for the first time at a late stage of the disease From the patient and his garments crusts and scabs should be removed with forceps, and placed in a dry, sterile, glass phial. All the available material should be collected An attempt to isolate virus should also be made, since crusts retain their infectivity for long periods of time

TABLE 11

LABORATORY DIAGNOSTIC PROCEDURES IN SMALLPOX

Day of Illness	*Clinical Condition*	*Material Available and Specimen Required*	*Test to be Performed*	*Duration of Laboratory Examination*
1	Fever, headache	Nil	Nil	Nil
2	Petechial "bathing drawers" or other prodromal rash	Scrapings from skin petechiae on slides	Microscopic examination for Paschen elementary bodies, electron microscopy	30 minutes
		In 1 c c of saline	Paul's test	2 3 days
			Isolation of virus in eggs and animals	4-10 days
3	Maculopapular eruption	as above	as above	as above
4 to 5	Vesicles	If vesicles are small, skin scrapings from base of 6 or more lesions to be made on glass slides.	Microscopic examination for Paschen bodies	30 minutes
		If vesicles are large and contain much fluid, fill capillary tubes	Complement fixation reaction	12–24 hours
		Vesicle fluid in capillary tubes	Paul's test	2–3 days
			Isolation of virus in eggs and animals	4–10 days
6 to 8	Pustules	Exudate from pustules in sterile screw-cap phial	Complement fixation tests	12–24 hours
			Flocculation test	12–24 hours
			Paul's test	2–3 days
			Isolation of virus in eggs and animals	4–10 days
9 to 14	Scabs	Desquamated epithelium to be gathered in a dry, sterile screw-cap phial	as above	as above

Technique of Tests

Examination for elementary bodies.

Films are stained by Paschen's, Gutstein's, Morosow's or other method (see Ch III). Microscopical examination shows very large numbers of small apparently spherical granules measuring 0 2 μ Granules of similar appearance and numbers would be found in a vaccinial lesion, but not in varicella van Rooyen and Illingworth (1944) used this method with considerable success in the Middle East campaign (see also Illingworth and Oliver, 1944) Downie (1946) also reports favorably. The test is applicable particularly to the early stages, before pustulation.

When facilities are available, electron microscopy affords a quick and accurate method of detecting the EB's of the variola-vaccinia group (Nagler and Rake, 1948, and personal observations)

Paul's test.

In 1916 (*a, b*) Paul introduced a laboratory test for the diagnosis of smallpox (see also, 1917 *a, b*, 1918, 1919) He recommended that the contents of variola

MILKER'S NODES

The condition, as its name implies, is acquired by milking *infected* cows, and, according to Bonnevie (1937), is characterized by the following clinical features The lesions usually develop on the hands and may commence as flat red papules (accompanied by pruritus) which in a week's time reach the size of a pea- or hazel-nut, appearing as well-defined hemispherical, reddish-blue, firm, elastic, and slightly tender nodules Suppuration next takes place, the fluid within then becomes absorbed, and the lesion flattens and disappears in a few weeks, but secondary infection and scar formation may develop in the more chronic forms of the illness
... any general disturbance of the patient's health, has been observed Cases have also been de-

The histological appearances of milker's nodes in certain respects resemble those seen in vaccinia, with the essential difference that in milker's nodes marked parakeratosis prevents the vesicles from rupturing

The etiology of the condition is obscure, but, according to Schultze *et al* (1927) and Stark *et al* (1934), the condition is due to infection with cowpox virus (see also Davies, Janes, and Downie, 1938, Tappeiner, 1938)

VACCINIAL INFECTION IN LABORATORY WORKERS

Workers in lymph institutes might be expected to be highly resistant to vaccinia Nevertheless vaccinal lesions may occur on the fingers and hands of persons shown to be highly immune by dermal tests (Broben and North, 1943; Horgan and Haseeb, 1944 *a*) These lesions clinically resemble milker's nodes or cowpox

KAPOSI'S VARICELLIFORM ERUPTION

Considerable interest has been taken in this condition, and a number of cases reported (e g , Juliusberg, 1898, Brown, 1934, McLachlan, 1934, Corson and Ludy, 1935, Goeckerman and Wilhelm, 1935).

It seems that at least 3 distinct disease entities are described under this title. In one group no virus can be isolated In the second group the etiological agent appears to be a member of the variola-vaccinia group, for Guarnieri bodies may be seen in the skin, and a virus with vaccinia-like properties may be isolated by suitable tests, such cases tend to occur in contacts of variola or vaccinia (Freund, 1934, Pepple, Murrell, and Fowlkes, 1942, Ronchese, 1943). The condition known as eczema vaccinatum may be identical with Kaposi's eruption

During the Glasgow 1942 outbreak of variola, 10 cases were seen, which, considering the rarity of the condition, argued for a connection with the variola-vaccinia group, the crusts of 2 cases gave positive serological tests (McKenzie, 1943).

In the third group, the herpes febrilis virus may be isolated from the lesions, and neutralizing antibodies develop in convalescence (Blattner, Heys, and Harrison, 1944, 1945, Lane and Herrold, 1944, Wenner, 1944, Lynch, 1945, Jaquette, Convey, and Pillsbury, 1946, Barker and Hallinger, 1947, Kipping and Downie, 1948).

Barton and Brunsting (1944) suggest that Kaposi's dermatitis is a manifestation of an exaggerated reaction to the herpes virus in persons with an exudative diathesis

EPIDEMIOLOGY OF TRUE SMALLPOX AND ALASTRIM

Recent Geographical Distribution

In *Great Britain* in recent times, alastrim was prevalent in England and Wales, and in 1927 there were 14,767 cases, in 1935 there were no cases (see *Memorandum*

Inoculation of animals.

An attempt may be made, by inoculation of monkeys, to isolate the virus of variola from the vesicular or pustular contents. Torres and Teixeria (1934 a 1937), for example, have specially recommended inoculation of the skin of *M. mulatta* in the diagnosis of alastrim After a few days, histological preparations are made from the lesions and search is made for the characteristic inclusions. Similar methods may be applied to the diagnosis of variola major. It may be worth while inoculating rabbits dermally (see Ch. XXVIII).

Inoculation of eggs.

Of recent years, a number of authors has shown that the chorio-allantois is highly sensitive to the presence of variola virus, the membrane is inoculated with a suspension of material obtained from the skin lesion, after 3–4 days characteristic pocks develop, and EB's and inclusions can readily be found (for references see p. 346). The use of antibiotics may facilitate virus isolation.

Serological tests.

Of recent years the technique of the variola flocculation and complement fixation tests has been brought to a high level of perfection. By the application of these tests (fully described on p. 370), it is possible definitely to establish the variolar nature of scabs from suspected cases. These results unfortunately do not distinguish between vaccinia and variola.

Antibodies develop in convalescence, and may enable a retrospective diagnosis to be made. These antibodies develop, of course, also after vaccination, and this may complicate diagnosis

HUMAN COWPOX

Human cowpox is a relatively mild disease (in comparison with variola major or minor), which affects only dairymaids and others who handle the udders and teats of infected cows Owing to its very limited distribution, human cowpox presents no epidemiological problems from the public health administrative point of view Cowpox, nevertheless, is of immunological importance in view of the protection which it affords against variola, as originally shown by Jenner

Among the more recent clinical descriptions of cowpox in man, Cathie (1932), for example, has reported a case occurring in a previously vaccinated farmer's wife who acquired the disease as the result of handling an infected milch cow The earliest lesion was a small red spot about the size of a pin's head which appeared on the patient's fingers, and developed into a blister filled with clear fluid that gradually enlarged in size to about 1 centimeter in diameter. At this stage of the lesion the patient complained of pruritus, general malaise, swelling of the hands and elbows, and axillary adenitis Pustules were also present on the anterior and posterior aspects of the upper arms and calves of the legs, and a temperature reaching 100° F. was recorded Healing occurred quickly, and on the 7th day the majority of the lesions had dried up

Taylor (1932) mentions 2 cases of cowpox acquired by farm laborers, who had contracted the disease through milking an infected cow which had blisters on its udder and teats In one of these patients the lesions were distributed on the forearms, and in the other they were present on the face, it was of interest to note that both persons had been vaccinated some 15 years previously (see also Kaiser and Weinfurter, 1932, and Davies, Janes, and Downie, 1938, for other accounts)

Kaiser and Gherardini (1933–4) reported the development of firm red nodules on the fingers, hands, and face in addition to the usual vesicular lesions of cowpox

Vaccinia in man may be transmitted mechanically to cows, spread in them, and reinfect man, the clinical picture closely resembling natural cowpox (Gray, 1943)

MILKER'S NODES

The condition, as its name implies, is acquired by milking infected cows, and, according to Bonnevie (1937), is characterized by the following clinical features The lesions usually develop on the hands and may commence as flat red papules (accompanied by pruritus) which in a week's time reach the size of a pea- or hazel-nut, appearing as well-defined hemispherical, reddish-blue, firm, elastic, and slightly tender nodules Suppuration next takes place, the fluid within then becomes absorbed, and the lesion flattens and disappears in a few weeks, but secondary infection and scar formation may develop in the more chronic forms of the illness The condition does not give rise to any general disturbance of the patient's health, although occasionally lymphangitis has been observed Cases have also been described by Becker (1940)

The histological appearances of milker's nodes in certain respects resemble those seen in vaccinia, with the essential difference that in milker's nodes marked parakeratosis prevents the vesicles from rupturing

The etiology of the condition is obscure, but, according to Schultze *et al.* (1927) and Stark *et al* (1934), the condition is due to infection with cowpox virus (see also Davies, Janes, and Downie, 1938, Tappeiner, 1938).

VACCINIAL INFECTION IN LABORATORY WORKERS

Workers in lymph institutes might be expected to be highly resistant to vaccinia Nevertheless vaccinial lesions may occur on the fingers and hands of persons shown to be highly immune by dermal tests (Brohen and North, 1943, Horgan and Haseeb, 1944 *a*) These lesions clinically resemble milker's nodes or cowpox.

KAPOSI'S VARICELLIFORM ERUPTION

Considerable interest has been taken in this condition, and a number of cases reported (e g, Juliusberg, 1898, Brown, 1934, McLachlan, 1934, Corson and Ludy, 1935, Goeckerman and Wilhelm, 1935).

It seems that at least 3 distinct disease entities are described under this title. In one group no virus can be isolated In the second group the etiological agent appears to be a member of the variola-vaccinia group, for Guarnieri bodies may be seen in the skin, and a virus with vaccinia-like properties may be isolated by suitable tests, such cases tend to occur in contacts of variola or vaccinia (Freund, 1934, Pepple, Murrell, and Fowlkes, 1942, Ronchese, 1943) The condition known as eczema vaccinatum may be identical with Kaposi's eruption

During the Glasgow 1942 outbreak of variola, 10 cases were seen, which, considering the rarity of the condition, argued for a connection with the variola-vaccinia group, the crusts of 2 cases gave positive serological tests (McKenzie, 1943)

In the third group, the herpes febrilis virus may be isolated from the lesions, and neutralizing antibodies develop in convalescence (Blattner, Heys, and Harrison, 1944, 1945, Lane and Herrold, 1944, Wenner, 1944, Lynch, 1945, Jaquette, Convey, and Pillsbury, 1946, Barker and Hallinger, 1947, Kipping and Downie, 1948)

Barton and Brunsting (1944) suggest that Kaposi's dermatitis is a manifestation of an exaggerated reaction to the herpes virus in persons with an exudative diathesis

EPIDEMIOLOGY OF TRUE SMALLPOX AND ALASTRIM

Recent Geographical Distribution

In *Great Britain* in recent times, alastrim was prevalent in England and Wales, and in 1927 there were 14,767 cases, in 1935 there were no cases (see *Memorandum*

on Smallpox, 1938). *Until recently, variola major has been rare, but "imported"* smallpox occurred in 1929 in Glasgow, and in Blackburn in 1934. During and since the Second World War there have been numerous importations of variola major into the British Isles. *The main recorded outbreaks are as follows:*

1942 Glasgow (Macgregor, 1942, Macgregor and Peters, 1942);
Edinburgh (Clark, 1944);
Fife (Fyfe and Fleming, 1943; Health Bulletin, 1943); Sutherland (1943) discussed the epidemiology of these outbreaks

1944, a hospital in Middlesex (Bradley, Davies, and Durante, 1946).

1946, Essex (Boul and Corfield, 1946); Merseyside (Peirce, 1947; Srallybrass, 1947); and more generalized, there being a total of 15 separate importations (Maddock and Conybeare, 1946; Bradley, 1947, Lancet, 1947).

These outbreaks were usually attributed to one or other of the following sources:

1. A case, often misdiagnosed, arriving by ship from India or the Middle East, and giving rise to infection in other passengers or crew.
2. A misdiagnosed case in a general hospital.
3. Infection from highly vaccinated persons, recently returned from abroad, developing modified smallpox.
4. Arrival by air of passengers in the incubation period of smallpox (see *Lancet*, 1946, Smith, 1948).

In *North America* the mild variety of smallpox is the prevailing clinical type (see Chapin and Smith, 1932, Dauer, 1946). Smallpox was very rare between 1932–

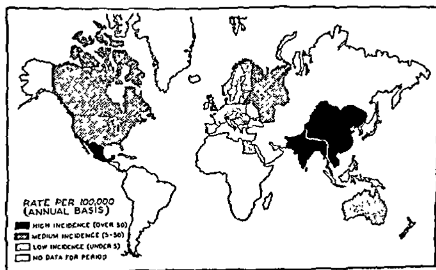

FIG 27 The world incidence of smallpox and alastrim (Hedrich, 1936). (Reproduced by courtesy of the Director of Public Documents, Washington)

1946, but recently there have been outbreaks of variola major (see Palmquist, 1947, Weinstein, 1947).

In many parts of the *Middle East and Africa*, both forms of smallpox are endemic, and frequently epidemic In the Second World War, a number of cases occurred in service personnel (van Rooyen and Illingworth, 1944; Illingworth and Oliver, 1944, Norris, 1944, Easton, 1945)

British India is the principal endemic focus of Asia There is a maximal inci-

dence in April. There is a rough 7-year cycle, peaks having occurred in 1927 and 1934 (see League of Nations, 1940).

Hedrich (1936) published the map illustrating the world incidence of the disease shown in Fig 27 and the information in Table 12.

Valuable information on the recent world incidence of smallpox has been published by the League of Nations (1934, 1943, see Fig 27), by the United Nations (1946), and by UNRRA (1945).

Mode of Spread and Pathogenesis

The case of smallpox is highly infective to unvaccinated contacts The infective agent persists in the skin lesions till the final stages, so that the case remains infective for an unusually prolonged period Infection may be transmitted by touch, or by fomites contaminated with saliva or by the skin, e g, wearing-apparel, bedclothes, cutlery, and crockery.

Variola virus in dried crusts may survive for over a year (Downie and Dumbell, 1947 *a*). Therefore the sickroom may become infected, and the virus survive therein for a prolonged period Downie and Dumbell actually isolated virus from the sweepings of a ward floor near the bed of a case. Flies play a considerable part in the dissemination of infection in the tropics.

It is probable that more usually cases of smallpox give rise to infection in close contacts by means of infected droplets of oral and nasopharyngeal secretion The question of whether infection can be spread more remotely by the air has been

much debated It is probable that droplet nuclei may be concerned (see the observations of Curshmann, 1875; Ker, 1920), and it has been a general belief that infection can be transferred over some distance, hence the siting of special smallpox hospitals. Millard (1944) has reviewed the evidence and suggests that it is stronger than often imagined, such a method of spread would explain the occurrence of cases without any apparent contact with a previous sufferer. Sabongy on the contrary (1923) does not believe that the virus can be conveyed through the air for any great distance, and cites the experience in the Government Fever Hospital, Cairo, where smallpox cases are nursed close to other compounds In Edinburgh in the 1942 epidemic, cases were nursed in a separate portion of the general fever hospital, but at no great distance from fully occupied wards, without any evidence of infection being conveyed

An important source of infection is the highly modified, perhaps ambulant, case of smallpox occurring in the immune person It is probable that such persons are the usual source of infections appearing without any evident contact with the fully developed disease. There is some evidence that healthy contacts may act as carriers (*Le Bourdellès, Lesaffre, and Rogez, 1946*).

There is a risk to undertakers dealing with corpses, and those engaged in disinfecting homes and fomites may contract the infection (Boul and Corfield, 1946)

It would appear that in the majority of cases, the infective agent enters the body by the nasal or buccal mucosa (see Blaxall, 1930).

Climatic Conditions and Smallpox

In India, Rogers (1926), by charting the average monthly smallpox mortality of 8 provinces together with the monthly rainfall, mean temperature, and both the relative and the absolute humidity or aqueous vapor tension (the last being the actual amount of moisture in the air measured by its pressure in terms of mercury, and essentially a measure of combined heat and moisture), has shown that the closest relationship exists between the last-named factor and the incidence of smallpox. *Thus the disease declined to its minimum with the rise of absolute humidity* to its maximum of 0 800 to 0.950

In England, Rogers (1928) has demonstrated the existence of a somewhat similar state of affairs during the years 1921 to 1927, when the mild type of smallpox was prevalent, he was able to correlate the case incidence with the prevailing climatic conditions Thus, a low absolute humidity favored the disease, and a high absolute humidity checked it He also pointed out that, in England, the mean temperature curve closely followed the absolute humidity curve and accordingly a cold winter and spring was a likely factor in the increase of cases.

The Control of Smallpox

The methods used in the control of smallpox, based on isolation and vaccination, have been admirably presented by Butterworth (1942), and the following account is partly based on his recommendations

Isolation.

The patient must be isolated, as infectivity persists till the lesions have healed It has been usual to isolate cases in special smallpox hospitals sited at a distance from other dwellings (For details regarding the planning, designing, and siting of [illegible] 1935, or other textbook on Public Health) [illegible] of variola major, it was shown that cases [illegible] the general fever hospital in cottages only 85 feet from fully occupied wards (Clark, 1944). The following precautions were taken All patients and staff in the hospital were vaccinated All admissions were vaccinated during the epidemic. The nursing staff were specially chosen, and also performed domestic duties. During the outbreak, they did not leave the grounds of

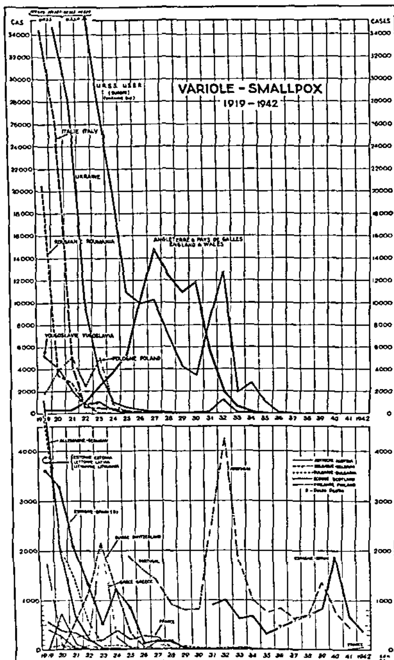

FIG 28 Chart showing incidence of smallpox in Europe, 1919-1942 (Reproduced from *Week Epidem. Rec*, 1943, *18*, 117, by courtesy of United Nations Health Organization)

the smallpox unit. Laundry was washed out in the unit and carbolized before going to the hospital laundry.

It must not be forgotten that ambulance drivers and similar staff must also be protected by vaccination.

It may be advisable to nurse smallpox patients on burnable mattresses, the excreta should be carbolized before disposal (see Conybeare, 1939, Gordon, 1939 *b*).

Disinfection.

The home of the case must be disinfected, e g, with formalin, and the bedding and clothing steam-treated. The personnel carrying out these tasks must be protected by recent vaccination.

Surveillance and vaccination of contacts.

A complete list of contacts must be made, including those less intimately exposed, such as tradesmen, and colleagues at the place of employment. These contacts should be vaccinated or revaccinated unless they have been done successfully very recently. Wherever possible they should be subjected to surveillance by officers of the Health Department, being visited daily for 3 weeks A medical officer should visit all contacts reported as showing illness. It may be feasible to take all intimate contacts into a reception house (see, e.g, Clark, 1944).

Common lodging houses and hostels.

These establishments should be visited during times of epidemic prevalence, as merchant seamen, vagrants, and similar persons are not infrequently concerned in the spread of smallpox

Schools.

Cases are of course excluded till pronounced free of infection Contacts are excluded for 21 days unless recently successfully vaccinated (Memorandum on *Closure of and Exclusion from School, 1942*). The head teacher should be instructed to send a daily list of absentees to the health department

Mass vaccination.[1]

As has been shown, the "sheet-anchor" of the control of smallpox is the application of vaccination to all contacts, close and remote. As long as an outbreak is of small dimensions, and contacts can be traced in each patient with a previous case, there is little necessity to embark on a mass vaccination campaign, with its attendant risks of postvaccinal encephalitis and other less serious complications. However, when the outbreak begins to spread, and when cases appear where no evident contact can be traced, it is usual to recommend the introduction of a mass vaccination campaign The spread of smallpox is capricious, and sometimes when the disease breaks out under conditions apparently very favorable for spread, this does not eventuate (Bradley, Davies, and Durante, 1946) The situation must therefore be carefully assessed before the decision to undertake a campaign of vaccination of the general public is taken.

For many years Millard has been opposed to a policy of general vaccination in a community as a means of checking the spread of smallpox in Britain (see 1943 *a*, *b*, 1945 *a*, *b*). He would concentrate on the vaccination of known contacts as the means of bringing an outbreak under control, and does not believe that there is much risk of the epidemic getting out of hand He feels that both the Edinburgh and Glasgow (1942) outbreaks were in fact already on the wane when mass vaccination was introduced

[1] The technique and principles of vaccination are discussed in Chapter XXXIV.

Seaport quarantine procedure.

In every seaport, laws exist for dealing with outbreaks of smallpox on ships entering that harbor Although individual regulations vary, in general they entail examination and compulsory vaccination of contacts, followed by a period of surveillance, *disinfection of clothing may be carried out* (Draper, 1925, Smith and Hart, 1925) Hutchison (1945), on the basis of his experience as a Port Medical Officer, questions the value of surveillance of contacts, which throws a heavy strain on the staff of health departments

...se to vaccina-

convenience,

action of immunity (+ to ++++). The Station does not accept a + reaction either for release or issue of certificate of "immunity." The reaction must be more definite (Hooker, 1925).

The International Sanitary Convention (1944) *laid down the following recommendations*

ARTICLE 42

Ships which have had a case of smallpox on board either during the voyage or at the *time of arrival may be subjected to the following measures*

1. Medical inspection.
2. The patients shall immediately be landed and isolated
3. Other persons reasonably suspected to have been exposed to infection on board, and who, in the opinion of the sanitary authority, are not sufficiently protected by recent vaccination, or by a previous attack of smallpox, may be subjected to vaccination or to observation or to surveillance, or to vaccination followed by observation or surveillance,

and which the sanitary authority regards as infected shall be disinfected

The ship shall immediately be given free pratique

For the purpose of this Article "recent vaccination" shall be taken as meaning evidence of successful vaccination not more than 3 years or less than 14 days previously, or evidence of an immune reaction.

It rests with each Government to take after disembarkation the measures which it considers appropriate to secure the surveillance of persons who are not protected by vaccination, and who arrive on a ship that had no smallpox on board, but left a local area where smallpox was epidemic less than 14 days before Vaccination of such persons may be performed

ARTICLE 43

It is recommended that ships calling in countries where smallpox is epidemic, shall take all precautions possible to secure the vaccination or revaccination of the crew and passengers

It is also recommended that Governments should make vaccination and revaccination as general as possible, especially in ports and frontier regions

Airport quarantine restrictions.

In order to check the possible spread of smallpox by aircraft, legislation has been laid down by the International Sanitary Convention for Aerial Navigation (1933, amended 1944), and Article 35, which relates to smallpox, reads as follows.

ARTICLE 35

(a) If there has not been a case of smallpox on board, no sanitary measure may be carried out save in the case of persons who have within 14 days left a local area where

smallpox is epidemic and who, in the opinion of the sanitary authority, are not sufficiently immunized. Such persons may be subjected, without prejudice to the terms of Article 52, to vaccination, or to surveillance, or to vaccination followed by surveillance, the period of which shall not exceed 14 days from the date of arrival of the aircraft.

(b) The following measures are applicable if there is a case of smallpox on board

1. medical inspection,
2. the sick shall be immediately disembarked and isolated,
3. *other persons reasonably suspected to have been* exposed to infection and who, in the opinion of the sanitary authority, are not sufficiently protected by recent vaccination, or by a previous attack of smallpox, may be subjected to vaccination or to observation or to surveillance, or to vaccination followed by observation or surveillance, the period of observation or surveillance being specified according to the circumstances, but in any event not exceeding 14 days, reckoned from the date of arrival of the aircraft,
4. linen, personal effects, and other articles which the sanitary authority considers to have been recently infected, shall be disinfected,
5. the parts of the aircraft which have been occupied by persons suffering from smallpox and which the sanitary authority considers to be infected shall be disinfected

For the purpose of this Article "recent vaccination" shall be taken as meaning *evidence of successful vaccination not more than* 3 years or *less than* 14 days previously, or evidence of an immune reaction

Recommendations of the British Ministry of Health.*

In an official publication entitled a *Memorandum on Smallpox* (1938) the Ministry of Health issued the following instructions summarizing the procedures which should immediately be adopted by a Medical Officer of Health in the event of smallpox appearing in his district:

1 The Medical Officer of Health should visit the patient with the medical practitioner in charge of the case with a view to satisfying himself as to the diagnosis If the patient is found to be suffering from smallpox, he should at once be removed to a smallpox *hospital*

2. The Medical Officer of Health should report the matter forthwith, preferably by telegram, to the Ministry of Health, as required in London by Article 14 (5) of the Sanitary Officers Order, 1926, and outside London by Article 17 (7) of the Sanitary Officers (outside London) Regulations, 1935

3 Vaccination or revaccination should be offered to contacts In doing so the following considerations should be kept in mind The duration of the incubation of smallpox is about 12 days counting to the onset of illness, that is, an average period of 14 days before the outcrop of the characteristic focal rash If this period is divided into three intervals comprising 7 days, 3 days, and 4 days, then past experience suggests that a *successful vaccination* in the first interval will wholly prevent the attack, in the second it will more or less modify the eruption, and in the last it will have no influence on the development and course of the disease The pertinent date is not when vaccination is performed but when the reaction begins, if the reaction, which should be manifest on the third or fourth day, is delayed by any cause, then the rise of immunity is deferred For this reason prevention can only be ensured by vaccination done within a day or two of exposure and followed by a normal reaction

4 Contacts should be kept under medical surveillance for a period of 16 days after the last exposure to infection For this purpose it is seldom necessary or desirable to isolate them in their homes

5 The Medical Officer of Health should at once inform the Public Vaccinators and Vaccination Officers of the name and address of every case of smallpox as it occurs, in order that all practical methods may be taken to secure prompt vaccination or revaccination of persons willing to avail themselves of this protection

County Councils, County Borough Councils and Metropolitan Borough Councils are responsible for the administration of the Vaccination Acts in their respective areas, and in a county district the Medical Officer of Health should report his action to the County Medical Officer of Health

* Current American practice does not appear to differ in any important respect (see A P H A , *Control of Communicable Diseases*, 1945)

The Medical Officer of Health is himself empowered by the Public Health (Smallpox Prevention) Regulations, 1917, to vaccinate or revaccinate contacts

6 The infected house and its contents, together with the clothing of all persons known to have been in close contact with the patient, should be disinfected In variola minor a less stringent standard of disinfection may be adopted at the discretion of the Medical Officer of Health.

7. It is important that all doubtful cases of the disease should at once be seen by the Medical Officer of Health, and, with this end in view, medical practitioners should be notified of the presence of the disease in the district, and invited to inform the Medical Officer of Health promptly of any cases suspected to be smallpox

8 In this connection the possible confusion with chickenpox should be borne in mind, as should also the fact that this disease can be made compulsorily notifiable by the Local Authority on the advice of the Medical Officer of Health, in accordance with the procedure set out in Section 147 of the Public Health Act, 1936, and Section 305 of the Public Health (London) Act, 1936

9 The Medical Officer of Health should notify the Medical Officers of Health of adjoining areas of the occurrence of smallpox, in order that they may take any precautionary measure which the circumstances require

10 In order to ascertain the source from which the case of smallpox derived infection, careful inquiry should be made concerning the movements of the patient during the three weeks preceding the commencement of his attack, and particularly on the 12th, 13th and 14th days prior to the onset of his illness. In this way, a case of smallpox which has not previously been recognized may be discovered

11 Public Vaccinators and Medical Officers of Health can secure a gratuitous supply of lymph on application by letter, telegram or telephone[1]

[1] Lymph is available from the major public health laboratories throughout the country.

CHAPTER XXVIII

THE VARIOLA-VACCINIA VIRUS: ANIMAL EXPERIMENTS

A. ANIMAL EXPERIMENTS WITH VARIOLA VIRUS

In this section we shall describe animal experiments carried out with the virus that can be isolated from cases of true smallpox (variola major). This we shall refer to simply as "variola virus."

Monkeys

A number of persons has succeeded in transmitting the causal agent of variola major to monkeys, usually employing the contents of vesicles or pustules of cases as inocula. The infection can be passaged, the original variola becoming transformed into vaccinia (e.g Zuelzer, 1874,[1] Copeman, 1893–4 *a*, *b*, 1902–3; de Haan, 1896, Park, 1902; Roger and Weil, 1902, Magrath and Brinckerhoff, 1904 *b*; Brinckerhoff and Tyzzer, 1906, Gauducheau, 1911; Blaxall, 1923, Gordon, 1925, Clearkin, 1928–9, Yaoi, 1936 *b*, Horgan, 1938). *M. rhesus*, *M. fuscatus*, cynomolgus, and cercopithecus monkeys have been employed, and the orang-utan is susceptible (Brinckerhoff and Tyzzer, 1906).

Routes of inoculation.

Monkeys can be infected by all the common routes. After application of virus-containing material to the scarified skin, or intradermal injection, typical lesions, which will shortly be described, develop. After intravenous injection, a generalized eruption may follow in about 5 days After corneal inoculation, a typical keratitis, closely resembling that of vaccinial infection, develops. Virus may be applied to the scarified lip, nose, or palate, when pustules develop (Brinckerhoff and Tyzzer, 1906). The same authors found that infection followed inhalation of virus, or intratracheal injection, pneumonia and generalized lesions might develop

Course of the disease after inoculation of the skin The animal is usually febrile, the temperature being maximal at the end of the first week, but returning to normal by the end of the second. The primary skin lesion can usually first be noted from the 3rd to the 5th day after inoculation as a slightly red indurated crusted area By the 7th to 8th day it is much larger, measuring up to 3 cm in diameter, and there is a central crust The lesion gradually diminishes, so that the crusts have desquamated by the 12th to 14th day The lymph glands are usually enlarged on the 4th to 5th day

Comparison of variolar and vaccinial lesions after dermal inoculation Copeman (1893–4 *a*, *b*) reported that the following differences can be observed in rhesus monkeys inoculated with variola and vaccinia viruses

(*a*) The variolar lesions are more or less crusted *de novo*

(*b*) There is less vesiculation with variola than vaccinia.

(*c*) With variola a generalized eruption may appear after 9 to 11 days, and cover the whole body.

(*d*) The final scab is not so raised in variola

(*e*) T[illegible] ained, in variola

(*f*) [illegible] less active, have suf- [illegible] not fatal

Horgan and Haseeb (1939) report that the potency of variolous material for the skin is only 1/1,000, that of vaccinia is considerably more

[1] References are appended at the conclusion of Ch XXXV, p. 403 et seq

Generalized lesions in variola infection. A generalized eruption, after infection by various routes, sometimes develops about the 8th to 11th day, and lasts for about 5 days (see in particular Brinckerhoff and Tyzzer, 1906). The face is most commonly involved, and later the wrists, scrotum, anus, palms, soles, inner aspects of the arms and thighs are affected. Such generalization is unusual (Blaxall, 1930).

Pathology of the skin lesions.

A. Primary. Brinckerhoff and Tyzzer (1906) give the following description of the histological changes in variolar infection of the monkey's skin In the earlier lesions (first 3 days) degenerative changes begin in the lines of scarification, Guarnieri bodies can be found in the malpighian cells. From the 3rd day onward there is extensive degeneration of epithelial cells, this is preceded by swelling and proliferation At the same time fluid is found between the epithelial cells, producing cavities. A dissolution of the swollen and degenerate epithelial cells aids in the formation of vesicles. Polymorphs increase in number and convert the vesicle into a frank pustule. The lesion is now covered by a thick crust.

The corium shows proliferation and swelling of the endothelial cells of the lymphatics and blood vessels At a later stage necrosis occurs beneath the center of the lesion, and associated therewith is an increase in the endothelial cells, Guarnieri bodies can be found in these cells.

The final stage is one of repair, epithelium grows in from the sides, and up from the hair sheaths to displace the crust.

B. Generalized. Brinckerhoff and Tyzzer (1906) report that the epithelial changes are similar to those in the primary eruption. The reaction in the corium is, however, very much less pronounced, there being no edema or necrosis, but only enlargement and proliferation of the endothelial cells, there is infiltration with polymorphs.

Rabbits

Variola cannot usually be transmitted to the rabbit by the dermal or intradermal routes directly from the human patient, although Risel (1919), Clearkin (1928–9), and Amies (1932) have reported positive results; usually a number of transfers are needed before the virus "takes" on the rabbit's skin Recently, Horgan (1938) obtained pustules after inoculation with human material, but passage by the dermal or intradermal route did not succeed. Rabbits can be directly infected with variola by other routes, however, e g, the anterior chamber (Komiyama, 1932), the testis (see Bachmann and Biglieri, 1922, Horgan, 1938), and, of course, via the cornea (Paul's test, see Ch. XXVII).

Calves

It is generally conceded that variola virus cannot usually be propagated in the skin of calves directly from the human patient, *repeated transfers through the calf* may, however, succeed After passage through monkeys or rabbits, the virus produces a slight lesion on dermal inoculation of the calf, if dermal passage is then continued, lesions develop

Other Animals

Teissier *et al* (1931) failed to produce any definite lesions in asses by dermal or intratesticular injection, earlier, however, Chaumier and Belin (1913) had claimed *that variola could be passed directly.*

Pigs may develop a slight local lesion after variolization of the skin, but the infection cannot be passed in series (Wurtz *et al*, 1913) More recently, Teissier *et al.* (1931) failed altogether to transmit variola

Warlomont (1883) claimed to have infected horses by intravenous injection. No lesions were produced in young bulls by intratesticular or dermal inoculation

CHAPTER XXVIII

THE VARIOLA-VACCINIA VIRUS: ANIMAL EXPERIMENTS

A. ANIMAL EXPERIMENTS WITH VARIOLA VIRUS

In this section we shall describe animal experiments carried out with the virus that can be isolated from cases of true smallpox (variola major). This we shall refer to simply as "variola virus."

Monkeys

A number of persons has succeeded in transmitting the causal agent of variola major to monkeys, usually employing the contents of vesicles or pustules of cases as inocula. The infection can be passaged, the original variola becoming transformed into vaccinia (e.g. Zuelzer, 1874,[1] Copeman, 1893–4 *a*, *b*, 1902–3; de Haan, 1896, Park, 1901, Roger and Weil, 1902, Magrath and Brinckerhoff, 1904 *b*, Brinckerhoff and Tyzzer, 1906; Gauducheau, 1911; Blaxall, 1923, Gordon, 1925; Clearkin, 1928–9, Yaoi, 1936 *b*, Horgan, 1938). *M. rhesus*, *M. fuscatus*, cynomolgus, and cercopithecus monkeys have been employed, and the orang-utan is susceptible (Brinckerhoff and Tyzzer, 1906).

Routes of inoculation.

Monkeys can be infected by all the common routes. After application of virus-containing material to the scarified skin, or intradermal injection, typical lesions, which will shortly be described, develop After intravenous injection, a generalized eruption may follow in about 5 days. After corneal inoculation, a typical keratitis, closely resembling that of vaccinial infection, develops. Virus may be applied to the scarified lip, nose, or palate, when pustules develop (Brinckerhoff and Tyzzer, 1906) The same authors found that infection followed inhalation of virus, or intratracheal injection, pneumonia and generalized lesions might develop.

Course of the disease after inoculation of the skin The animal is usually febrile, the temperature being maximal at the end of the first week, but returning to normal by the end of the second. The primary skin lesion can usually first be noted from the 3rd to the 5th day after inoculation as a slightly red indurated crusted area. By the 7th to 8th day it is much larger, measuring up to 3 cm in diameter, and there is a central crust The lesion gradually diminishes, so that the crusts have desquamated by the 12th to 14th day The lymph glands are usually enlarged on the 4th to 5th day

Comparison of variolar and vaccinal lesions after dermal inoculation Copeman (1893–4 *a*, *b*) reported that the following differences can be observed in rhesus monkeys inoculated with variola and vaccinia viruses.

(*a*) The variolar lesions are more or less crusted *de novo*.
(*b*) There is less vesiculation with variola than vaccinia
(*c*) With variola a generalized eruption may appear after 9 to 11 days, and cover the whole body
(*d*) The final scab is not so raised in variola.
(*e*) The temperature rise is more marked, and longer sustained, in variola.
(*f*) The variola-infected animals suffer from diarrhea, are less active, have suffused eyes, and emit an unusual odor, the disease is not fatal.

Horgan and Haseeb (1939) report that the potency of variolous material for the skin is only 1/1,000, that of vaccinia is considerably more

[1] References are appended at the conclusion of Ch XXXV, p 403 et seq

Dermal strains of virus are usually maintained by passage through calves, sheep, or rabbits, the animals being inoculated by scarification. When the lesions reach sufficient size, the area bearing them is scraped and vaccinial pulp obtained. Other terms used to refer to this type of virus are "dermovaccinia," "dermovaccine," "dermal vaccine," "lymph," "dermal lymph," and sometimes merely "pulp" The terms "lapine," "dermal lapine," and "dermolapine" refer to dermal vaccinia from the rabbit. Sometimes passage is carried out through human beings, when the term "humanized lymph" is used

Ledingham and McClean's (1928) Strain

These authors propagated testicular and dermal strains of vaccinia by intradermal inoculation, in rabbits Virus, when passed by this route, lost most of its potency as tested by scarification Potency increased markedly, however, when tested by intradermal inoculation; for example, the dermal inoculum might develop at least 100,000 times its original virus content The histological reactions produced by this strain are described on p 316.

Armstrong's Heat-resistant Strain

Armstrong (1929 *a*) injected dermal virus intratesticularly, after each inoculation virus was heated at 37 5° C. By continued selection and propagation, he secured a strain of virus which showed an increase of several hundred per cent in the length of time it would withstand heat This virus was used in experiments on intratracheal injection, when it was found to produce a pure virus pneumonia (Armstrong and Lillie, 1929).

Noguchi's Strain of Testicular Virus

Noguchi's (1915, 1918) experiments were initiated with the object of securing a bacteria-free suspension of vaccinia. He began by injecting rabbits intratesticularly with dermal vaccine At first, passage proved difficult, but after 10 transfers the virus was successfully established The usefulness of Noguchi's method was soon recognized, and testicular virus has been widely used in all types of experiment with vaccinia virus since that date The following other terms are applied to testicular virus· "testilapine," "orchilapine," the term "neurovirus" is also used, for certain strains of virus are often passed both intracerebrally and intratesticularly. Noguchi (1918) found that prolonged testicular passage did not lower the activity of the virus for the skin, though increasing activity for the testis, he also showed that testicular virus had no more tendency to localize in the internal organs on intravenous inoculation than had dermal vaccine. Testicular passage is frequently employed to increase the virulence of dermal or other strains of virus that have become of reduced potency

Neurovaccinia

A strain of virus widely used in experimental work is one which is maintained by cerebral passage in rabbits, with perhaps occasional testicular passage To a strain of this type, the terms "neurovaccine," "neurovaccinia," or neurovirus" are applied The worker primarily associated with the study of neurovaccine is Levaditi, who with Nicolau and other co-workers has carried out much experimental work (Levaditi, Harvier, and Nicolau, 1921, Levaditi and Nicolau, 1921, 1922 *a*, *b*, 1923 *a*, *d*, *e*, Levaditi, 1924, Levaditi *et al*, 1927, 1937, 1938 *a*, *b*)

Production of neurovaccinia.

Starting with a strain of dermal virus, the French authors carried out cerebral passage in rabbits, difficulty was experienced at first, and some testicular transfers had to be interpolated, but eventually virus could be passed by the cerebral route alone Certain workers have found, however, that some strains of virus can be

(Teissier *et al.*, 1931). Teissier *et al* (1930) found that the cat was only very slightly susceptible to variola. It has been claimed that variola can be passed in buffaloes (Gauducheau, 1911). Nelson (1940 *a*) found transient lung changes in mice on nasal instillation

B. ANIMAL EXPERIMENTS WITH ALASTRIM VIRUS

Monkeys

Numerous investigators have carried out *experiments on the transference of* alastrim virus to monkeys (Green, 1915–17, Leake and Force, 1921; Blaxall, 1923, van Hoof, see Jorge, 1924, Gordon, 1925, Ledingham, 1926 *a*, Turkhud and Pandit, 1926–7, Amies, 1932; Torres and Teixeria, 1933 *a*, *b*, 1934 *a*, da Cunha and Teixeria, 1934, Torres, 1935–6) As a general rule, it has been found that lesions develop after application of virus directly to the scarified skin, and after intradermal injection, the reaction is similar to that produced by variola virus (*vide supra*), histologically, however, the inclusion bodies may be differentiated (see p. 340) Monkeys can also be infected by intravenous injection, when skin lesions develop on the face and limbs

It would appear that on occasions some difficulty may be realized in transmitting the infection (Ledingham, 1926 *a*, Turkud and Pandit, 1926–7, Horgan and Haseeb, 1939)

Rabbits

A number of authors has tested the susceptibility of rabbits to alastrim virus (MacCallum and Moody, 1921, Moody, 1922, Blaxall, 1923, Jorge, 1924, Gordon, 1925, Ledingham, 1926 *a*, Turkhud and Pandit, 1926–7, McKinnon and Defries, [illegible] 928, Torres, 1935–6) The majority found that [illegible] skin produces either no result, or at most a [illegible], however, *definite lesions develop, resembling* those of vaccinia It appears that by the intradermal route a local eruption may develop on direct inoculation of human material (see Ledingham, 1926 *a*, McKinnon and Defries, 1928).

The rabbit's cornea is, of course, susceptible, and a positive Paul's test can often be elicited (Torres, 1935–6, Paul's test, see above)

Other Animals

Usually, lesions are not produced on application of human alastrimic material to the skin of calves (MacCallum and Moody, 1921, Blaxall, 1923, Turkhud and Pandit, 1926–7) Occasionally, however, a mild reaction may be noted (see Green, 1915–17) Cleland and Ferguson (1915) were able to secure a "take" after a few transfers Blaxall (1923) found that, using virus passed through monkeys and rabbits, definite lesions developed after a few transfers through the calf

Ledingham (1926 *a*) produced a reaction by intradermal inoculation of the guinea-pig's pad, De Korté (1904) and Green (1915–17) did not succeed in infecting these animals, however Van Breuseghem (1940) adapted virus to mice after rabbit passage

C. VACCINIA VIRUS

Variants of Vaccinia

Vaccinia exists usually as a virus with dermal properties, proliferating abundantly in skin, but only poorly in the brain A number of variants has been produced by passage under abnormal circumstances Findlay (1936) regards these as *Dauermodificationen* Levaditi *et al* (1940 *a*) regard EB suspensions as complexes containing variants of different potential pathogenicity and tissue affinity Adaptation to a particular host favors one variant at the expense of others

Dermal strains of virus are usually maintained by passage through calves, sheep, or rabbits, the animals being inoculated by scarification. When the lesions reach sufficient size, the area bearing them is scraped and vaccinal pulp obtained Other terms used to refer to this type of virus are "dermovaccinia," "dermovaccine," "dermal vaccine," "lymph," "dermal lymph," and sometimes merely "pulp." The terms "lapine," "dermal lapine," and "dermolapine" refer to dermal vaccinia from the rabbit. Sometimes passage is carried out through human beings, when the term "humanized lymph" is used.

Ledingham and McClean's (1928) Strain

These authors propagated testicular and dermal strains of vaccinia by intradermal inoculation, in rabbits Virus, when passed by this route, lost most of its potency as tested by scarification Potency increased markedly, however, when tested by intradermal inoculation, for example, the dermal inoculum might develop at least 100,000 times its original virus content. The histological reactions produced by this strain are described on p. 316.

Armstrong's Heat-resistant Strain

Armstrong (1929 *a*) injected dermal virus intratesticularly, after each inoculation virus was heated at 37.5° C. By continued selection and propagation, he secured a strain of virus which showed an increase of several hundred per cent in the length of time it would withstand heat. This virus was used in experiments on intratracheal injection, when it was found to produce a pure virus pneumonia (Armstrong and Lillie, *1929*).

Noguchi's Strain of Testicular Virus

Noguchi's (1915, 1918) experiments were initiated with the object of securing a bacteria-free suspension of vaccinia He began by injecting rabbits intratesticularly with dermal vaccine At first, passage proved difficult, but after 10 transfers the virus was successfully established The usefulness of Noguchi's method was soon recognized, and testicular virus has been widely used in all types of experiment with vaccinia virus since that date. The following other terms are applied to testicular virus, "testilapine," "orchilapine," the term "neurovirus" is also used, for certain strains of virus are often passed both intracerebrally and intratesticularly. Noguchi (1918) found that prolonged testicular passage did not lower the activity of the virus for the skin, though increasing activity for the testis, he also showed that testicular virus had no more tendency to localize in the internal organs on intravenous inoculation than had dermal vaccine. Testicular passage is frequently employed to increase the virulence of dermal or other strains of virus that have become of reduced potency

Neurovaccinia

A strain of virus widely used in experimental work is one which is maintained by cerebral passage in rabbits, with perhaps occasional testicular passage To a strain of this type, the terms "neurovaccine," "neurovaccinia," or neurovirus" are applied The worker primarily associated with the study of neurovaccine is Levaditi, who with Nicolau and other co-workers has carried out much experimental work (Levaditi, Harvier, and Nicolau, *1921*, Levaditi and Nicolau, 1921, *1922 a, b*, 1923 *a, d*, e, Levaditi, 1924, Levaditi *et al*, 1927, 1937, 1938 *a, b*)

Production of neurovaccinia.

Starting with a strain of dermal virus, the French authors carried out cerebral passage in rabbits, difficulty was experienced at first, and some testicular transfers had to be interpolated, but eventually virus could be passed by the cerebral route alone Certain workers have found, however, that some strains of virus can be

more readily converted into neurovaccinia than was the case in Levaditi's experiments (see p. 317). Blanc and Caminopetros (1923) actually claimed that one corneal passage of dermal vaccine was sufficient to convert it into neurovaccinia Levaditi and Voet (1937) have shown that egg passage rapidly conferred on 2 dermal strains the properties of neurovaccinia. A feebly encephalitogenic mixture of dermotropic EB's and a few neurovaccinal EB's became transformed into fully virulent neurovaccinia by egg passage (Levaditi *et al.*, 1939 *a*).

Some properties of neurovaccinia.

During the first 100 intracerebral passages, 85 per cent. of rabbits died after 4 to 7 days, and 77 per cent. after 4 to 6 days; 4 per cent. died on the 3rd day following injection. During the second 100 passages, 72 per cent. died on the 4th or 5th day, and 14 per cent. on the 3rd day; this indicated a considerable increase in virulence (Levaditi, 1924). It is this property of increase in activity over dermal lymph that has caused neurovaccine to be so widely used in experimental work.

Neurovaccinia can be transmitted to numerous animals, and Levaditi and Nicolau (1923 *a*) summarized these results as follows: the virus is infective for rabbits, guinea-pigs, rats, mice, calves, and monkeys by the cutaneous route, it is infective for rabbits, guinea-pigs, cats, and monkeys by the cerebral route. Smith, Horgan, and Haseeb (1941) reported on the properties of the Lagos mouse neurovaccinia. This was of high virulence for the mouse and rabbit cerebrally, but retained full dermotropic potency.

Other properties will be alluded to below.

The tissue affinities of neurovaccinia.

Although Levaditi originally held that neurovaccine was endowed predominantly with an affinity for the ectoderm, this opinion has been revised as follows (Levaditi *et al.*, 1938 *a*) In vaccinia virus there are held to be 2 components, "E" and "M", "E" affects the ectoderm, and "M" the mesoderm. Dermal virus, for example, does not readily produce a reaction on cerebral injection, nor does it produce a reaction in the pleural and peritoneal cavities on local injection. In this case, the "E" component completely masks "M." Neurovaccine, however, produces severe cerebral changes, and the pleuroperitoneal reaction. With this strain, "M" is the dominant component. During the conversion from dermovaccine to neurovaccine, the relative content of these 2 factors undergoes an alteration. Probably the receptivity of the reticulo-endothelial systems of the central nervous system of the host plays the part of a selector in securing this change. They have also shown that the encephalitogenic power of a strain may vary from *récolte* to *récolte*; further, some rabbits are relatively insusceptible to vaccinia by intracerebral injection, possibly due to a previous attack of rabbit-pox (1938 *b*)

The biological nature of neurovaccinia.

Elsewhere it has been described how rabbits may sometimes develop a spontaneous infection known as rabbit-pox (see p 323). Although the causal agent of this condition is evidently related to the variola-vaccinia group, it appears to be independent Now, since rabbits can contract such a disease spontaneously, it may be asked whether neurovaccinia is not in reality a strain of rabbit-pox virus modified by repeated passage (see Borrel, 1936)

Levaditi and Voet (1937) were able to show that 2 bovine viruses could be transformed into neurovaccinia by egg passage, without the aid of rabbits. It is unlikely, therefore, that rabbit-pox virus is the original source of neurovaccinia

Levaditi regarded neurovaccinia as a fixed virus, for passage on the rabbit's skin did not alter it back to dermovaccine, nor did passage through the human skin effect any change (Nicolau and Poincloux, 1924). This view has been recently upheld by Levaditi, as he has shown that 5 transfers by dermal inoculation of

monkeys induced no alteration in the characters of the virus (Levaditi *et al*, 1937). Douglas, Smith, and Price (1929), however, maintained that testicular passage altered the properties of neurovaccinia to a certain extent. First, intradermal reactions were much more constantly elicited Second, the testicle-passed virus had a much greater virulence for the peritoneum and bladder. Third, generalization was induced with greater constancy.

It may be said that there is some doubt in the minds of many whether neurovaccinia is as distinct from dermal virus as is, for example, fixed from street rabies virus It is felt that the greater activity of neurovaccinia may be due merely to the fact that it proliferates much more luxuriantly in the brain than does dermal virus in the skin. Levaditi (1939*a*) has shown that the number of EB's in the minimal infective dose is much less in neurovaccinia than in dermal vaccinia.

Cultured Virus

Of recent years strains of both dermo- and neuro-virus have been grown in tissue culture and in the egg (see Chs XII, XIII). Although certain changes may be induced by growth *in vitro* or in the egg, as a general rule no radical differences in properties develop.

ANIMAL EXPERIMENTS WITH VACCINIA VIRUS

Rabbits

These animals have been more extensively used in experimental work than any other animal, their susceptibility being originally demonstrated by a number of early workers (Gailleton, 1889, Bard and Leclerc, 1891, Calmette and Guérin, 1901, Henseval and Convent, 1910). It has been stated that young animals are more susceptible than older ones (see Ørskov and Andersen, 1938*a*). The reaction of the rabbit after inoculation by various routes, as well as certain other experiments, will now be described.[1]

ROUTES OF INOCULATION

Dermal inoculation.

Rabbits are readily infected by direct application of vaccinia virus to the freshly shaved skin, and by scarification of depilated skin. The area selected is usually the back, but Tyzzer (1904) recommended the internal surface of the ear. It is convenient to rub the virus into the skin by means of a glass rod. The lesions usually first appear from the 3rd to the 7th day, the earliest evidence of reaction being red papules Vesicles, which soon coalesce, are usually noted by the 5th day; pustulation occurs and scabs form. After cutaneous inoculation, the higher the dilution of virus the larger is the vesicle produced, and the fewer vesicles there are, the number of vesicles in proportion to the amount of virus increases in the higher dilutions (Groth and Munsterer, 1935)

Titration of virus. Virus is often titrated by application to the scarified skin, and the following instructions of Gordon (1925) should be followed

(*a*) Rabbits should weigh 1,500 to 2,000 gm
(*b*) The test fluid is diluted in saline, e g, from 1/1,000 to 1/1,000,000.
(*c*) A drop of the test fluid is placed on the shaved skin, and scratches made through the drop with a sharp surgical needle.
(*d*) The lesions become evident from the 3rd to 7th day.
(*e*) To remove pulp the animal is killed and bled, the carcass is left for a period, to allow the remaining blood to clot The shaved area of the skin

[1] The description of "generalized vaccinia" which may follow inoculation of virus by various routes is given on p 321. The distribution of virus throughout the body of the infected animal after various types of inoculation is discussed on p 322

more readily converted into neurovaccinia than was the case in Levaditi's experiments (see p. 317). Blanc and Caminopetros (1923) actually claimed that one corneal passage of dermal vaccine was sufficient to convert it into neurovaccinia Levaditi and Voet (1937) have shown that egg passage rapidly conferred on 2 dermal strains the properties of neurovaccinia. A feebly encephalitogenic mixture of dermotropic EB's and a few neurovaccinal EB's became transformed into fully virulent neurovaccinia by egg passage (Levaditi *et al.*, 1939 *a*).

Some properties of neurovaccinia.

During the first 100 intracerebral passages, 85 per cent. of rabbits died after 4 to 7 days, and 77 per cent. after 4 to 6 days, 4 per cent. died on the 3rd day following injection. During the second 100 passages, 72 per cent. died on the 4th or 5th day, and 14 per cent. on the 3rd day, this indicated a considerable increase in virulence (Levaditi, 1924). It is this property of increase in activity over dermal lymph that has caused neurovaccine to be so widely used in experimental work.

Neurovaccinia can be transmitted to numerous animals, and Levaditi and Nicolau (1923 *a*) summarized these results as follows· the virus is infective for rabbits, guinea-pigs, rats, mice, calves, and monkeys by the cutaneous route; it is infective for rabbits, guinea-pigs, cats, and monkeys by the cerebral route. Smith, Horgan, and Haseeb (1941) reported on the properties of the Lagos mouse neurovaccinia This was of high virulence for the mouse and rabbit cerebrally, but retained full dermotropic potency.

Other properties will be alluded to below.

The tissue affinities of neurovaccinia.

Although Levaditi originally held that neurovaccine was endowed predominantly with an affinity for the ectoderm, this opinion has been revised as follows (Levaditi *et al*, 1938 *a*)· In vaccinia virus there are held to be 2 components, "E" and "M", "E" affects the ectoderm, and "M" the mesoderm. Dermal virus, for example, does not readily produce a reaction on cerebral injection, nor does it produce a reaction in the pleural and peritoneal cavities on local injection. In this case, the "E" component completely masks "M." Neurovaccine, however, produces severe cerebral changes, and the pleuroperitoneal reaction. With this strain, "M" is the dominant component. During the conversion from dermovaccine to neurovaccine, the relative content of these 2 factors undergoes an alteration. Probably the receptivity of the reticulo-endothelial systems of the central nervous system of the host plays the part of a selector in securing this change. They have also shown that the encephalitogenic power of a strain may vary from *récolte* to *récolte;* further, some rabbits are relatively insusceptible to vaccinia by intracerebral injection, possibly due to a previous attack of rabbit-pox (1938 *b*)

The biological nature of neurovaccinia.

Elsewhere it has been described how rabbits may sometimes develop a spontaneous infection known as rabbit-pox (see p 323). Although the causal agent of this condition is evidently related to the variola-vaccinia group, it appears to be independent Now, since rabbits can contract such a disease spontaneously, it may be asked whether neurovaccinia is not in reality a strain of rabbit-pox virus modified by repeated passage (see Borrel, 1936).

Levaditi and Voet (1937) were able to show that 2 bovine viruses could be transformed into neurovaccinia by egg passage, without the aid of rabbits It is unlikely, therefore, that rabbit-pox virus is the original source of neurovaccinia

Levaditi regarded neurovaccinia as a fixed virus, for passage on the rabbit's skin did not alter it back to dermovaccine, nor did passage through the human skin effect any change (Nicolau and Poincloux, 1924). This view has been recently upheld by Levaditi, as he has shown that 5 transfers by dermal inoculation of

monkeys induced no alteration in the characters of the virus (Levaditi *et al.*, 1937).

Douglas, Smith, and Price (1929), however, maintained that testicular passage altered the properties of neurovaccinia to a certain extent: First, intradermal reactions were much more constantly elicited Second, the testicle-passed virus had a much greater virulence for the peritoneum and bladder Third, generalization was induced with greater constancy.

, and scratches made

(*e*) To remove pulp the animal is killed and bled, the carcass is left for a period, to allow the remaining blood to clot. The shaved area of the skin

[1] The description of "generalized vaccinia" which may follow inoculation of virus by various routes is given on p. 321 The distribution of virus throughout the body of the infected animal after various types of inoculation is discussed on p 322.

is removed, and the lesions are scraped off. The pulp is weighed and any desired amount of saline added to give a definite known dilution Finally, it is placed in a bottle with 10 per cent. of ether and stored in the cold

Pathology.

1. *Tyzzer's* (1904) *experiments* Tyzzer examined the histological findings after scarification of the internal surface of the rabbit's ear. After 4 to 8 days the skin was reddened, the surface being elevated and somewhat opaque; if pricked, lymph exuded. After a further 1 to 2 days, the lesion increased in extent, and severe itching was experienced Histologically, after 3 days the skin was seen to be increased to 2 or 3 times its normal thickness The blood vessels and lymphatics were dilated, the endothelium of the smaller vessels was proliferated. Numerous polymorphs and lymphocytes infiltrated the tissues, and there was an increase of connective tissue cells. The malpighian cells showed vesicular change, Guarnieri bodies could be found in the cells outside the vesicles The surface of the lesion was covered by a crust composed of the horny layer with polymorphs and fibrin

2. *Levaditi and Nicolau* (1923 *a*) compared the skin lesions produced by neuro- and dermo-vaccines. Neurovaccine produced an erythematous reaction which, on the 3rd day, was followed by a *more or less confluent papular eruption.* The lesions of neurovaccine were more swollen, redder, more infiltrated, more intense, and deeper. When the neurovaccinal papules were beginning to become pustular, the dermovaccinal had progressed to umbilication and suppuration Later, the neurovaccinal lesions became confluent, the surface underwent dry necrosis, and a thick scab formed which lasted for weeks, the dermovaccinal lesion, on the contrary, scabbed quickly after becoming pustular Microscopically, the dermal strain showed a greater tendency to involve connective tissue

3. *Ledingham* (1924) studied the histology of the rabbit's skin after infection by scarification, with a view to determining the primary tissue response to vaccinia (see also p 329) The earliest change was an involvement of the capillaries in the papillary region, the deep dermis being only slightly involved The malpighian cells and hair follicles were severely disorganized by subjacent exudate Diffuse and perivascular infiltrations were the predominant feature of the response

4. *Andervont* (1926 *b*) drew attention to the formation of the vaccinal vesicles, at first subdivided into compartments by elongated epithelial cells, but later becoming monolocular owing to destruction of these cells He also referred to changes in the corium, such as infiltration with polymorphs, capillary dilatation, and thickening of the capillary walls

5. *Amies's* (1938) *experiments with crude lapine* Amies described the lesions produced by crude lapine inuncted through the shaved skin Almost no lesions were found at 24 hours, but after 48 hours the epidermal cells had proliferated to form a layer 6 to 10 deep Many cells showed early "balloon" degeneration Small eosinophilic bodies less than 1 μ in diameter were found in the cytoplasm In some cases these bodies were larger, and the cells containing them showed disintegration, these necrotic areas were invaded by polymorphs that surrounded the eosinophilic bodies After 72 hours round-cell infiltration of the dermis, first seen earlier, had become more marked The malpighian layer was now 15 cells deep in some areas, much "ballooning" being present Inclusions could only be found in a few cells at the edges of the large areas of eosinophilic necrotic material At their bases these areas were invaded by polymorphs and other inflammatory cells, the hair follicles also showed invasion by polymorphs and cellular proliferation

After 4 days the epidermis was almost completely replaced by strongly acidophilic material Inclusions could be found in the hair follicles, both in the more healthy cells and lying free between those that were degenerate The round-cell infiltration of the dermis was more pronounced

6. *Amies's* (1938) *experiments with elementary bodies* Amies also studied the

reaction after application of homogeneous suspensions of elementary bodies (see p. 329) to the shaved skin.

Compared to the reaction produced by crude lapine, these lesions were seen to be milder; inclusions occurred more frequently, and dermal infiltration was much less marked.

The vaccinial inclusion first developed as a small eosinophilic granule about 0.5 μ in diameter, in the perinuclear space of the epidermal cell, 48 hours after infection. Two or more such bodies were often seen in any one cell, in the later stages these granules were considerably larger. Some cells were literally packed with bodies, and it was noted that the nuclei of cells containing inclusions remained intact till a late stage.

Intradermal injection.

Rabbits can be infected readily by intradermal injection, this route was probably popularized first by Novotny and Schick (1910). Characteristic papulopustular lesions, which eventually undergo scabbing, develop in 3 to 5 days

Vaccinia virus can be simply titrated by intradermal injection of serial dilutions from 1/10 to 1/1,000,000, an average titer of dermal virus being 1/10,000 to 1/100,000 Ledingham (1924) found that with lymph diluted 1/100, the reaction might not be visible for 3 days, although with lower dilutions it might be evident in 24 hours, the reaction after inoculation of a 1/10,000 dilution did not appear for 3 to 6 days (see also Clearkin, 1930) Titrating EB suspensions, Henderson and McClean (1939) found the titer by scarification 1 100 of that obtained by intradermal inoculation

After intracutaneous injection, it was found that no virus could be demonstrated locally from 20 minutes to 20 hours after the inoculation, but thereafter virus increased gradually to reach a maximal concentration (Widelock, 1938) He found that the same maximum was reached whether the original inoculum was diluted 1/100 or 1 1,000,000 As might be expected, the greater the concentration of virus injected the sooner was this maximum attained He showed also that the size of the reaction varied with the bulk of the inoculum. The severity of the reaction did not depend on the quantity, but on the concentration of the inoculum, for example, the injection of 0 01 c c or 0 5 c c of the same concentration produced a reaction of equal intensity

Groth and Munsterer (1935) reported that when rabbits were inoculated with falling dilutions of vaccinia, the area of infiltration did not decrease in proportion to the degree of dilution. In fact, with reference to the amount of virus, the area was considerably increased in higher dilutions

Ledingham (1926 *b*) showed that the reaction to vaccinia injected intracutaneously could be annulled, or very considerably reduced, by simultaneous injection of India ink This effect also operated if virus was injected into areas of skin previously infiltrated with ink

Passage of vaccinia by the intradermal route Ledingham and McClean (1928) carried out experiments on the propagation of testicular and dermal vaccinia by the intracutaneous route After passage the virus lost most of its potency when tested by scarification For example, material giving a titer of 1 1,000 to 1 10,000 by intradermal injection, only produced a reaction on scarification when diluted 1 10 Barg and Rudenko (1935) confirmed these observations

Pathology

1. *Ledingham* (1924) carried out an extensive series of observations on the reaction of the rabbit's skin to the intradermal inoculation of lymph.

After 6 hours polymorphs were found to infiltrate the cells of the hair follicles The venous channels of the dermis were congested and often filled with poly-

morphs. The dermis (excepting the papillary region) was infiltrated with polymorphs, and there was slight edema of the tissue spaces.

After 24 hours the polymorphs in the follicles showed karyorrhexis; in the dermis there were more polymorphs. The endothelial cells of the capillaries in the papillary region and overlying skin muscle were "frayed-out," and showed occasional mitoses. Endothelioid cells from the adventitia were engulfing dead polymorphs.

After 2 days the malpighian cells showed some infiltration with polymorphs The dermis showed the beginning of a division into 3 layers The central layer showed degenerate polymorphs and necrotic or hyaline tissue fibers; there were occasional large vessels, the walls of which were infiltrated with polymorphs. Fibrin threads could also be seen; some of the vessels in the central zone showed complete coagulation necrosis of the walls, with a surrounding fibrinous exudate Above and below this central zone were dense infiltrations of polymorphs, adventitial cells engulfing these, and small vessels from whose sheaths adventitial cells were produced.

After 3 days definite chromatolysis and swelling of some of the malpighian cells were observed In the dermis the central zone was very distinct, and consisted of finely comminuted polymorph chromatin and isolated necrotic vessels There was active proliferation of adventitial cells over the skin muscle, and through the perimysium.

After 4 days "ballooning" of the malpighian cells was seen, with some chromatolysis The deeper parts of the hair follicles were often replaced by young vascular tissue with many adventitial cells showing mitoses In the dermis the main change was that new vascular tissue was being formed actively in the boundary zones

After 7 days the malpighian cells were shrunken and showed numerous mitoses In the dermis the central zone was being invaded by the newly formed vascular tissue from above and below. In many places, adventitial cells showed perivascular cuffing, mitoses were common, and a few plasma cells were seen.

After 10 days the only abnormality in the epidermis was the destruction of the deeper portions of the hair follicles. In the dermis the central zone was much thinner, and young connective tissue fibers were being laid down at its margins. The vessels in the peripheral zones were widely cuffed.

After 15 days there was follicular regeneration, the central zone being now entirely replaced by histiocytes and young connective tissue fibers

2 *Lesions produced by Ledingham and McClean's* (1928) *strain* The dermal reaction was seen to be essentially similar to that produced by ordinary lymph, the primary attack being on the vascular endothelium, later, there was an infiltration with polymorphs and a mobilization of histiocytes. Necrotic changes took place in these cells, and the nuclear debris occupied a large area of the mid-dermis There was evidence of reticulo-endothelial involvement in the perivascular sheath, also, more diffusely, in the neighborhood of the larger vessels of the upper papillary layer and skin muscles, and also throughout the skin muscles and areas of dermis peripheral to the central lesion Hemorrhagic necroses were frequent along the course of vessels running up through the mid-dermis to the papillary layer The lymph glands draining the inoculated areas were red, swollen, and might show definite discrete hemorrhages.

3 *Thompson and Buchbinder's* (1932) *experiments* These workers carried out a series of tests using the following strains two nonencephalitogenic strains of virus (Noguchi's testicular virus and the NY strain of calf lymph), Mulford's [illegible] passage in rabbit brains, and finally Leva- [illegible] as follows The two nonencephalitogenic [illegible] age, and only slight edema and necrosis Resolution began after 144 to 168 hours Secondary lesions were few, and occurred

after about 144 hours, the animals never died as a result of these injections. The reactions produced by the 3 encephalitogenic strains were, however, very different. Hemorrhages occurred with Mulford's rabbit brain strain and Levaditi's strain; edema and necrosis were severe in all cases. Resolution began after 168 to 192 hours with both Mulford's strains, but after 144 to 192 hours with Levaditi's After 96 hours secondary lesions were marked and extensive with Mulford's strains, being only slight with Levaditi's virus. Death occurred frequently after inoculation of Mulford's rabbit brain strain, but not with the other two.

Subcutaneous injection.

Rabbits can be infected by the subcutaneous route, and if the dose is sufficiently large, a generalized eruption may develop It is said that if virus is injected in a large volume of water, a greatly swollen infiltrated mass develops giving a large yield of virus (Blanc and Caminopetros, 1924 *a*).

Ledingham (1924) studied the pathological features of injection of lymph into the groin By the 3rd day a hard mass had developed near enlarged glands. On the 6th day hemorrhage was seen in the subcutis, and there were yellowish tracts of exudate overlying the muscle tissue, and extending to the dermis above the skin muscle These tracts consisted of polymorph debris and adventitial cells containing polymorphs; they were surrounded by large areas of embryonic vascular tissue containing newly formed capillaries Some capillaries contained blood, while extensive hemorrhages were seen near others Between the capillaries there were large numbers of adventitial cells There was no involvement of the epidermis

Intracerebral injection.

There is considerable individual variation between vaccinial strains in the facility with which they can be transmitted to rabbits by intracerebral injection, and many authors have referred to this point (see Bachmann and Biglieri, 1923 *b*, Zurukzoglu, 1927, Herrmar [illegible]

For examp [illegible] of experimenters have failed to prod [illegible] and have been unable to carry on [illegible] 8–9, Grinker, 1930–1, Beattie and Potter, 1934). Pette and Kornyey (1933) could not discover changes resembling those of human postvaccinal encephalitis after injection into the cisterna magna Other workers, however, have been more successful For example, Marie (1920) carried out intracerebral injection of dermal vaccinia and passed the virus in series. He found that the virus spread to the lowest part of the cord, and the animals usually died between the 5th and 8th day. Condrea (1922 *b*) found that rabbits injected intracerebrally with dermal lymph developed nervous symptoms, and that the virus could be passed and become of exalted virulence.

Gordon (*Report*, 1928) produced encephalitis in rabbits by an intracerebral, followed by an intravenous, injection of lymph Virus could usually readily be demonstrated in the brains of rabbits dying within 10 days, but not in those dying after 12 to 13 days. McIntosh (1928) produced encephalitis by using a highly virulent dermal lymph. Blanc and Caminopetros (1931) found that corneal passage of dermal lymph resulted in the production of a strain which, on intracerebral injection, produced encephalitis.

Although the dermal strain of the New York Health Department produced no symptoms on intracerebral injection, Mulford's lymph induced a severe and [illegible]

injection Using the same strain in 1929, however, success was achieved.

A considerable advance was made in the study of vaccinia virus when it was shown that intracerebral passage could be readily carried out if the original inocu-

lum had been passed intratesticularly; further, success was more easily secured if an occasional testicular passage was interpolated in the cerebral series (Levaditi, Harvier, and Nicolau, 1921, 1922). It is now firmly established that rabbits develop meningo-encephalitis after injection of neurovirus, whether the inoculum is infected testis or brain (McIntosh and Scarff, 1930, Hurst and Fairbrother, 1930, Spooner, 1930).

Pathology.

A number of workers has described the pathological changes induced by neurovaccinia or virulent dermal virus (Condrea, 1922 *c*, Levaditi, 1924, McIntosh and Scarff, *1930, Spooner, 1930, Hurst and Fairbrother, 1930; Bardach, 1931; Force,* Beattie, and Lucia, 1939). The meninges are congested, contain small hemorrhages, and there is perivascular cuffing with mononuclear and plasma cells Guarnieri bodies occur in nerve and ependymal cells. The brain proper shows some perivascular cuffing, and degeneration of nerve cells Miliary abscesses may occur. McIntosh (1928) described the changes in his experiments as like those in human postvaccinal encephalitis, but Spooner (1930) found no demyelination. The changes are mainly those of a meningitis, and to a less extent of encephalitis

The production of encephalitis by peripheral injection.

Mainly with a view to investigating the etiology of human postvaccinal encephalitis (see Ch. XXXV), a number of workers has tried to produce encephalitis in rabbits by injecting vaccinia peripherally. Certain authors have failed to produce any evidence of encephalitis after dermal, subcutaneous, corneal, intravenous, or intratesticular injection of various strains of virus (Zurukzoglu, 1927; Demme, 1928, Pette and Kornvey, 1933). Further, the effect of various traumata and injections directed toward causing the cerebral localization of the virus has been studied with negative results by the following authors Berger (1929) showed that *injury to the skin, and anesthesia, did not cause the virus to produce encepha*litis after dermal inoculation Hurst and Fairbrother (1930) were not able to produce encephalitis in rabbits by intradermal inoculation of ordinary lymph or neurovaccine, despite injection of nervous tissue intracerebrally, or horse serum intrathecally, in an attempt to localize the virus Szymanowski and Zand (1931) tried to facilitate the passage of virus to the brain after intratesticular injection by injecting rabbits with trypan blue to blockade the reticulo-endothelial system, no success was achieved.

Other workers have, however, been successful in their attempts to cause localization of virus in the brain by peripheral injection For example, although normally the intravenous injection of neurovaccine does not cause virus to appear in the brain, the intracerebral injection of saline or broth secures localization (Levaditi and Nicolau, 1923 *a*) Evidence of cerebral involvement after peripheral inoculation has been furnished by Blanc and Caminopetros (*1924 b, 1926*). After corneal, *cutaneous, subcutaneous, or intravenous inoculation of lymph,* animals developed encephalitic symptoms There was usually a rise of temperature, and if animals were killed at this time virus could be recovered from the brain It has been reported that encephalitis may sometimes develop in rabbits inoculated corneally with all types of virus (Levaditi and Nicolau, 1926) McIntosh and Scarff (1930), using a virulent neurovaccine, sometimes noted *meningo-encephalitis after intra*dermal inoculation, after intravenous injection this occurrence was somewhat more common. Grinker (1930–1) reported that after intratesticular injection a fatal meningo-encephalitis might develop

Corneal scarification.

After application of virus to the scarified cornea of the rabbit, an acute keratitis develops in 2 to 4 days The surface of the cornea becomes quite "steamy"

and, later, opaque. There is usually a considerable degree of mucopurulent conjunctival discharge The cornea shows a decreased transmission of light *in vitro* (Little *et al.*, 1947).

Pathology.

One of the best descriptions of the pathological features of vaccinial keratitis is that of Tyzzer (1904). Within 36 hours the scarification wound marks are obliterated by growth of epithelium. On the second day after infection the corneal surface is seen to be uneven and elevated at the scarification marks From this time onward some slight circumcorneal congestion is apparent. The cornea becomes "steamy," and there is purulent conjunctival exudate Histologically, after 4 to 8 hours the appearances do not differ from those due only to injury. After 16 hours inclusions occur in the vicinity of the nucleus of the epithelial cells (see also, Levaditi and Schoen, 1935) Some polymorphs can be found infiltrating the substantia propria After 50 hours the epithelium near the scarification marks is much proliferated and many inclusions can be found, in other areas the epithelium is very thin Some epithelial cells are seen to be included by others. Polymorphs are now quite numerous After 3 days there is still further epithelial proliferation, and Guarnieri bodies occur at a greater distance from the scarification Eosinophilic inclusions can be found in the fibroblasts of the substantia propria (Rhodes and van Rooyen, 1937 *a*). After 5 to 6 days the epithelium is 5 to 6 times its normal thickness, Guarnieri and fibroblastic bodies are less frequent, and many epithelial cells are included. At this stage, many of the infiltrating polymorphs become degenerate and disintegrate, liberating their granules From the 9th to 11th day Guarnieri bodies may be found in the epithelium, but are absent in some specimens

Intratesticular injection.

The rabbit can be infected with vaccinia by intratesticular injection, a method first introduced by Noguchi (1915, 1918), the value of which is now firmly established As a general rule, dermal lymph produces only a slight reaction; continued passage results, however, in the production of a strain with high affinity for testicular tissue

Noguchi (1915) found that after 48 hours the virus had increased approximately a hundredfold over its titer at the end of the first day and continued to increase for a few days

The value of the method was confirmed by Condrea (1922 *a*, *b*) and Ohtawara (1922). The peritoneal cavity may contain clear, straw-colored exudate of semigelatinous consistency (see Douglas, Smith, and Price, 1929).

Pathology

After intratesticular injection Noguchi (1915) found the following changes During the first 24 hours few changes were found in the testis, although there were microscopic foci of infiltration with polymorphs, and exudate in the interstitium After 48 hours the testis became swollen, congested, and edematous There was a heavy leukocytic infiltration in the interstitium and tubules, the tubules were filled with hydropic cells, after 3 days, the infiltration was even more marked Naked-eye, after 4 days, the testis was purplish-red, and spotted here and there with irregular yellowish areas, the organ was friable and there was exudate in the tunica vaginalis Histologically, at this period, there were several groups of tubules which had undergone total necrosis After 6 days the reaction had decreased somewhat, for there was less edema and cellular infiltration, by the 7th day the infiltration was resolving more rapidly By the 10th day the organ was reduced in size below its normal dimensions From the 12th to 18th days the organ became even more shrunken, and microscopically there was loss of testicular cells and collapse of tubules After 5 weeks there was complete parenchymal atrophy.

Intravenous injection.

This route of injection is most commonly used in order to produce generalized vaccinia. This syndrome is fully discussed on p. 321 and no more need be said here, except to quote some recent interesting work of Gordon (1939*a*), who recorded experiments on the production of fibrositis and arthritis with vaccinia virus Rabbits were injected intravenously on two occasions, at a 4-day interval If the dose of virus was too large, a polyarthritis developed, usually, however, there was a mono-arthritis of one hind leg. The lesion was essentially periarticular, and usually situated near the insertion of the Achilles tendon. If the rabbit was killed in the early stages, the subcutaneous tissues were filled with a serofibrinous exudate, at first, the virus was present in a dilution of 1:1,000,000, later only in 1.1,000, and by the 11th day it was absent. Virus was found in the popliteal gland draining the affected area, but was present in the blood and spleen only in small quantity. Histologically the lesions resembled those of rheumatic fibrositis in man.

Intraperitoneal injection.

Rabbits may be infected by the intraperitoneal route with neurovaccinia, producing an exudate in the peritoneal cavity, adhesion of the mesentery, and the formation of Guarnieri bodies in the mesentery and skin of the abdominal wall (Borrel, 1936). Douglas, Smith, and Price (1929) found that the surfaces of the gut and the peritoneum were stippled with hemorrhages.

Intrasplenic injection.

Ledingham (1924) adopted this route of inoculation in his work on the primary tissue reaction in vaccinia. At postmortem the capsule was thickened and dead white near the point of inoculation, nodules were found on the adjacent abdominal wall and the peritoneal coat of the large intestine. Histologically, the white plaques consisted of a loosely arranged reticulum of trabecular cells which extended in from the capsule and ramified through the organ At the margin there were isolated hemorrhages. The white plaque seemed to be the outermost *defensive line* of numerous primary karyorrhectic foci. These foci were immediately surrounded by actively dividing primary stem cells, and in the outer rows were many plasma cells.

Intra-oral inoculation.

Levaditi and Nicolau (1923*a*) infected the rabbit by swabbing the mouth with neurovaccinia, pustules were produced, and the saliva became infected.

Nasal instillation.

Gordon (1925) found that rabbits could be infected by this route, an acute catarrh developing after 6 to 8 days, the mucopurulent discharge contained the virus. The catarrh might spread to the conjunctival sacs. Following nasal instillation, it has been said that virus can be found in the cervical lymph after 12 hours, thereafter for 7 days virus enters the blood by the cervical lymph ducts, passing through the lymph glands *en route* (Yoffey and Sullivan, 1939)

Intratracheal injection.

After injection of neurovaccine, it was found that a rash might develop on shaved areas of skin (Levaditi and Nicolau, 1923*a*).

Armstrong and Lillie (1929) carried out experiments on the intratracheal injection of Armstrong's heat-selected strain The animals developed severe respiratory symptoms which usually proved fatal The appearances were those of virus pneumonia.

Injection by other routes.

Intrapleural injection. Bardach (1932 *b*) showed that rabbits injected intrapleurally with neurolapine died, with exudate on both the inoculated and uninoculated sides.

Intrapulmonary injection. Muckenfuss *et al* (1932) studied the effects of injecting vaccinia directly into the lungs At first the alveoli contained coagulated al-

Sciatic nerve injection Levaditi and Nicolau (1923 *a*) infected rabbits by injection into this nerve.

Injection into fetal rabbits Woolpert (1936, Woolpert and Gallagher, 1937) introduced the technique of injecting the head of the 20- to 40-day-old rabbit fetus, the uterus was delivered by laparotomy and the injection performed through the uterine wall After injection of neurovaccine, the virus disseminated widely and killed the fetus in 7 days, depending on the dose (see also Gallacher and Woolpert, 1940).

Generalized Vaccinia in Rabbits

Under certain circumstances, rabbits injected with vaccinia virus may develop lesions in many parts of the body, the condition being known as "generalized vaccinia" Numbers of authors have studied this phenomenon (Camus, 1917–18, Noguchi, 1918; Levaditi, Harvier, and Nicolau, 1921, Ledingham, 1924, 1928–9,

Hu, and Pearce, 1936 *c*). These lesions are particularly liable to develop after intravenous injection, but also after inoculation by other routes The lesions have been produced most commonly with neurovaccinia Ordinary dermal lymph only exceptionally gives rise to generalized lesions. Duran-Reynals (1929) found that about 25 per cent. of rabbits suffering from enhanced lesions due to the effect of testis extracts died from generalized vaccinia. Hasskó (1932) found that generalization was particularly apt to develop in animals subjected to repeated injections of iron acetate.

Lesions occur most commonly on the skin, often showing a tendency to localize on areas traumatized by shaving or irritants. This localization effect is often known after the names of Calmette and Guérin (1901), who injected virus intravenously and noted the development of lesions on the shaved skin Similarly, after intravenous injection, keratitis may develop if the cornea is scarified or exposed to x-rays (Levaditi and Nicolau, 1923 *a*)

Papules are commonly found at the mucocutaneous junctions, they also occur in the nostrils and air passages, mouth, lips and tongue, esophagus, anal mucosa, and genital region Keratitis, orchitis, and adenopathy may all occur. Lesions are often found in the thymus, spleen, and liver, and they may occur in the brain.

The pathology of generalized vaccinia

Douglas, Smith, and Price (1929) gave the following description of the naked-eye changes in generalized vaccinia The skin pock began as a small raised papule which became hard and nodular. Slightly later it became vesicular, and then umbilicated, centrally the pock was dark and punched out, due to necrotic changes

The liver and spleen showed, *in the early stages, round dull white spots, later,* there was a semitranslucent grayish zone, with a depressed white center, rarely, a narrow purple zone of congestion might form around the lesion. The lung lesions were at first punctate hemorrhagic spots, but when fully developed appeared as glistening grayish nodules, hemorrhage being seen in the center. McIntosh and Scarff (1929) regarded the changes as those of an infective granuloma affecting primarily the smaller blood vessels, there being endothelial proliferation, tissue necrosis, and later, fibrosis. (For other papers on the pathology of generalized vaccinia see Ledingham, 1924; Ledingham and Barratt, 1929, Stewart and Duran-Reynals, 1929)

Blood Changes in Infected Rabbits

It appears that workers have seldom reported on this question. Hinc (1926) described the following changes in the blood of rabbits inoculated cutaneously with vaccinia· hemolysis, and the presence of bilirubin; an invasion of normoblasts, and a lowering of the red cell count and hemoglobin level, mainly from the 3rd to 8th day; a polynucleosis began about the 4th day, and lymphocytosis about the 6th to 7th day, both these *reactions being over by the 11th day* Douglas, Smith, and Price (1929) described the following changes in 2 animals inoculated intravenously and developing generalized vaccinia: On the 2nd day after injection the number of red cells began to fall, and this continued till the 7th day, when the count was about half the normal. Then the count increased, to become normal from the 15th to 16th day. The color index was raised during the fall Normoblasts were found, especially shortly after injection. The total white count was reduced for 2 to 3 days, it then increased, to reach a maximum about the 9th day. The large mononuclears showed the greatest increase, polymorphs were increased to a lesser extent, while lymphocytes were definitely decreased, myelocytes were found from the start.

Distribution of Virus in Infected Rabbits

Brain and cord As would be expected, virus is found in the brain, and sometimes the cord, after direct intracerebral injection. It probably disappears from the brain fairly rapidly (10 days—Gordon, *Report*, 1928, see also Herzberg, 1931 *a*), on occasions, virus appears to remain for a long period—Perdrau (*Report*, 1928), in fact, finding it 7 months afterwards. Numerous authors have isolated virus from the brain, and less commonly the cord, of rabbits infected with vaccinia by routes other than intracerebral (Levaditi, Harvier, and Nicolau, 1921, Plotz, 1922, Blanc and Caminopetros, 1923, 1924 *b*, Levaditi and Nicolau, 1923 *a*, Barikine *et al*, 1924. Huon and Placidi, 1924, Lucksch, 1927, Zurukzoglu, 1927, McIntosh and Blaxall, see *Report*, 1928, Berger, 1929, Douglas, Smith, and Price, 1929, Cattaneo, 1930) This localization of vaccinia has been noted after injection of both dermo- and neuro-viruses by the following routes dermal, subcutaneous, corneal, intratesticular, intravenous, and intrasciatic

It has been found that the intracerebral injection of human brain tissue serves to localize vaccinia in the brain of infected animals (Levaditi and Nicolau, 1923 *c*, Levaditi, Lépine, and Troisier, 1928)

Cerebrospinal fluid Gildemeister and Hilgers (1930 *a*) isolated virus from the cerebrospinal fluid in 5 out of 34 rabbits after skin inoculation

Blood Vaccinia has been found in the blood of infected rabbits, although not very constantly (Ohtawara, 1922, Gildemeister and Heuer, 1927 *a*, 1928, McIntosh and Blaxall, see *Report*, 1928) It appears that an explanation for the failure of various workers to find the blood infective is now available, because Smith (1929) showed that virus present in blood, was rapidly removed by the blood cells In this way, whole blood appeared to be virus-free, but after fractionation virus was detected in the white cells He found vaccinia in the blood up to 8 days after in-

jection In an immune animal he found that it disappeared in 4 to 6 days. He concluded that this masking of virus in whole blood was due to the presence of im-
vaccinia virus was
noted that Douglas
"take up" vaccinia
virus *in vitro*. After direct intravenous injection virus could be demonstrated irregularly in the blood for up to 6 days (Douglas, Smith, and Price, 1929)

Certain experiments have also been conducted on the effect which blockading the reticulo-endothelial system with India ink or iron acetate has on the distribution of vaccinia virus in the blood (Hoen, Tschertkow, and Zipp, 1926, Gildemeister and Heuer, 1927 *a*; Goldman, 1927–8, Hasskó, 1932). It may be said that the results are at variance, and there is dubiety whether this operation has any effect in altering the occurrence of vaccinia in the blood, as compared with controls

Lymph and lymph glands After nasal instillation, virus can be found in the cervical lymph Centrifugation of this lymph at only 2,000 r p m has the effect of depositing the virus, in association with the lymphocytes, it can also be shown that lymphocytes fix virus *in vitro* (Yoffey and Sullivan, 1939) Virus may be found in lymph glands, especially in the regional glands after intracutaneous injection (Orskov and Andersen, 1938 *b*)

Other organs and fluids Vaccinia has, on occasions, been isolated from the following fluids and organs. liver (McIntosh and Blaxall, see *Report*, 1928), lungs (Ohtawara, 1922, Levaditi and Nicolau, 1923 *f*, Winkler, 1927), urine (Gildemeister and Hilgers, 1930 *a*); saliva (Levaditi and Nicolau, 1923 *a*); testis (Levaditi and Nicolau, 1923 *f*), ovary (Levaditi and Nicolau, 1923 *f*), amniotic fluid of pregnant animals (Blaker, 1936), mammary glands (Levaditi and Nicolau, 1923 *a*), adrenals, tongue, spleen, marrow, kidney, and heart (Douglas, Smith, and Price, 1929); nasal mucosa (Gins *et al*, 1929), nasal and buccal mucosae, larynx, trachea, esophagus, ileum, and bladder (Gordon, see *Report*, 1928) Pearce (1940) found virus might persist in the testis for 17 weeks after inoculation by various routes.

SPONTANEOUS VACCINIA AND RABBIT-POX

There have been a number of instances recorded where animals have contracted infection with a strain of vaccinia (or closely related virus) without, apparently, having been directly inoculated therewith In certain of these cases the virus isolated has proved to be an ordinary strain of neurovaccinia, in such instances it is probably correct to regard the condition as a neurovaccinial infection acquired spontaneously—spontaneous vaccinia In other cases the virus has been endued with unusual properties, and although resembling neurovaccinia has differed therefrom in certain respects, notably in its greater potency. On these occasions the disease is best regarded as "rabbit-pox"—a spontaneously acquired infection due to the virus of rabbit-pox

(*a*) Levaditi and Sanchis-Bayarri (1927), for instance, found that a rabbit inoculated with suspectedly syphilitic material developed a spontaneous vaccinial infection, a strain of neurovaccine being isolated The injected animal had been in the neighborhood of infected animals although it had itself never been inoculated with vaccinia

(*b*) Nicolau and Kopciowska (1929 *a*, *b*) described a spontaneous vaccinial malady in rabbits The animals suffered from a nasal discharge, conjunctivitis and orchitis were also noted, death usually occurred after 5 to 11 days, neurovaccinia virus was isolated from the brain, testis, and skin papules

(*c*) In a later communication (1931) they alluded to the presence of virus in the ovary, adrenal, lung, spleen, liver, brain, and blood In certain cases numerous vaccinial pustules were found on the lung surfaces, usually associated with a purulent pleuropneumonia Orchitis was also found In some cases pustules were present

The liver and spleen showed, in the early stages, round dull white spots, later, there was a semitranslucent grayish zone, with a depressed white center, rarely, a narrow purple zone of congestion might form around the lesion. The lung lesions were at first punctate hemorrhagic spots, but when fully developed appeared as glistening grayish nodules, hemorrhage being seen in the center. McIntosh and Scarff (1929) regarded the changes as those of an infective granuloma affecting primarily the smaller blood vessels, there being endothelial proliferation, tissue necrosis, and later, fibrosis. (For other papers on the pathology of generalized vaccinia see Ledingham, 1924; Ledingham and Barratt, 1929, Stewart and Duran-Reynals, 1929.)

Blood Changes in Infected Rabbits

It appears that workers have seldom reported on this question. Hine (1926) described the following changes in the blood of rabbits inoculated cutaneously with vaccinia. hemolysis, and the presence of bilirubin; an invasion of normoblasts, and a lowering of the red cell count and hemoglobin level, mainly from the 3rd to 8th day, a polynucleosis began about the 4th day, and lymphocytosis about the 6th to 7th day, both these reactions being over by the 11th day. Douglas, Smith, and Price (1929) described the following changes in 2 animals inoculated intravenously and developing generalized vaccinia: On the 2nd day after injection the number of red cells began to fall, and this continued till the 7th day, when the count was about half the normal Then the count increased, to become normal from the 15th to 16th day. The color index was raised during the fall. Normoblasts were found, especially shortly after injection. The total white count was reduced for 2 to 3 days, it then increased, to reach a maximum about the 9th day. The large mononuclears showed the greatest increase, polymorphs were increased to a lesser extent, while lymphocytes were definitely decreased, myelocytes were found from the start

Distribution of Virus in Infected Rabbits

Brain and cord As would be expected, virus is found in the brain, and sometimes the cord, after direct intracerebral injection. It probably disappears from the brain fairly rapidly (10 days—Gordon, *Report*, 1928, see also Herzberg, 1931 *a*); on occasions, virus appears to remain for a long period—Perdrau (*Report*, 1928), in fact, finding it 7 months afterwards Numerous authors have isolated virus from the brain, and less commonly the cord, of rabbits infected with vaccinia by routes other than intracerebral (Levaditi, Harvier, and Nicolau, 1921, Plotz, 1922, Blanc and Caminopetros, 1923, 1924 *b*, Levaditi and Nicolau, 1923 *a*, Bankine *et al.*, 1924; Huon and Placidi, 1924, Lucksch, 1927, Zurukzoglu, 1927; McIntosh and Blaxall, see *Report*, 1928, Berger, 1929, Douglas, Smith, and Price, 1929, Cattaneo, 1930) This localization of vaccinia has been noted after injection of both dermo- and neuro-viruses by the following routes dermal, subcutaneous, corneal, intratesticular, intravenous, and intrasciatic

It has been found that the intracerebral injection of human brain tissue serves to localize vaccinia in the brain of infected animals (Levaditi and Nicolau, 1923 *c*, Levaditi, Lépine, and Troisier, 1928)

Cerebrospinal fluid Gildemeister and Hilgers (1930 *a*) isolated virus from the cerebrospinal fluid in 5 out of 34 rabbits after skin inoculation

Blood. Vaccinia has been found in the blood of infected rabbits, although not very constantly (Ohtawara, 1922, Gildemeister and Heuer, 1927 *a*, 1928, McIntosh and Blaxall, see *Report*, 1928) It appears that an explanation for the failure of various workers to find the blood infective is now available, because Smith (1929) showed that virus present in blood, was rapidly removed by the blood cells In this way, whole blood appeared to be virus-free, but after fractionation virus was detected in the white cells He found vaccinia in the blood up to 8 days after in-

of vaccinia in monkeys after intracutaneous injection They found that the reaction appeared later than normal, was more necrotic, and healed more slowly. Extirpation of the spleen also caused retardation of the vaccinial process

The histological changes in the skin of the monkey infected with vaccinia are very similar to those produced by variola (see p. 308). Vesicular change occurs in the epidermis, and Guarnieri bodies can be found. Lesions are found in the dermis also, such as proliferation of the capillary endothelium and cellular infiltrations.

The Experimental Production of Encephalitis

A number of important papers has been published on the development of meningo-encephalitis in monkeys, following injection by intracerebral or other routes. This matter is of main interest in view of the claims that have been made for vaccinia virus as the etiological agent of postvaccinal encephalitis of man The papers will now be cited *seriatim*:

(*a*) *Levaditi, Nicolau, and Sanchis-Bayarri* (1927) found that monkeys developed meningo-encephalitis after intracerebral injection with neurovaccinia. Death usually occurred shortly after Histologically the lesions did not resemble those of postvaccinal encephalitis

[illegible]

corded changes in the central nervous system after dermal inoculation of a dermal strain of lymph. With large doses perivascular demyelination was noted.

(*d*) *Eckstein and Sarvan* (1930) failed to notice any nervous symptoms or to demonstrate histological changes in the brains of monkeys vaccinated intradermally and then subjected to certain procedures e g, chronic alcoholic intoxication, starvation, or splenectomy.

(*e*) *Hurst and Fairbrother* (1930) carried out experiments on the intracerebral injection of monkeys with a testicular strain of virus. They found that an early symptom of infection was nose-rubbing Then the animals became apathetic, and weakness developed on the contralateral side of the body, mainly the leg Jacksonian fits might occur, contralateral hemianopia and, later, complete blindness

[illegible]

granule cells. Enlargement of the glial cells was noted as early as the 3rd day. There was evidence of nerve cell degeneration, chiefly of the smaller cells, in the superficial layers, the changes had not, however, advanced to neuronophagia No evidence of demyelination, in any way comparable to that observed in human postvaccinal encephalitis, was seen

In addition, they carried out experiments in which monkeys were injected intradermally with ordinary vaccine lymph, or with neurovaccine; these animals were also injected intracerebrally with normal brain tissue, or intrathecally with horse serum, in an attempt to localize the virus None of these monkeys developed any lesions of consequence

(*f*) *Eckstein* (1931 *a, b*) showed that monkeys could be infected with vaccine lymph injected into the suboccipital space After 3 to 5 days the animals developed meningeal and encephalitic symptoms, and died between the 6th and 31st days (usually before the 10th) Histological examination showed evidences of a meningo-encephalomyelitis closely resembling human postvaccinal encephalitis

(*g*) *Eckstein* (1932 *b*) carried out experiments in which vaccine virus was injected intravenously, and the circulation of blood in the brain altered by the following maneuvers application of diathermy, unilateral ligature of the jugular vein,

in the meninges They found that numbers of rabbits became immune, due to an inapparent infection.

(*d*) Levaditi and Vaisman (1931) found that rabbits bearing experimental syphilomata might contract a spontaneous neurovaccinial infection when housed in the vicinity of infected rabbits.

(*e*) Bardach (1931) isolated a virus strain from a case of spontaneous vaccinial infection. This strain had the somewhat unusual property of producing pleurisy and peritonitis, with much exudate, in rabbits (1932 *a*). On intracerebral injection of mice a fatal meningo-encephalitis developed (1933).

(*f*) Pearce (1940) isolated vaccinia from the testes of 2 rabbits.

(*g*) *The Rockefeller Institute epizootics of rabbit-pox.* Perhaps the best known of all these types of outbreak occurred in the Rockefeller Institute, New York (*Greene, 1934 a, b, 1935 a, b, Rosahn and Hu, 1935; Hu, Rosahn, and Pearce, 1936,* Pearce, Rosahn, and Hu, 1936 *a, b*; Rosahn, Hu, and Pearce, 1936 *a, b, c*). Within a period of 2½ years the rabbit breeding colony at the Rockefeller Institute was visited by 3 separate epidemics of rabbit-pox. The disease was very fatal, especially in the younger stock; lymphadenitis, orchitis, a skin rash, and eye lesions were commonly found Focal necrotic changes occurred in the internal organs.

The disease was caused by the virus of rabbit-pox which has been studied in detail, and is probably closely related to that of vaccinia, especially neurovaccinia, although it cannot be held to be identical It is more potent than neurovaccinia and considerably more so than dermal culture virus. These differences between the 3 strains can be demonstrated by animal inoculation, serum neutralization tests, and cross inoculation tests.

The important question that arises out of this work is whether neurovaccinia is not in reality a rabbit-pox strain, or derived therefrom. Borrel (1936) has suggested that neurovaccinia may be rabbit-pox, but this suggestion has been strongly countered by Levaditi *et al* (1938), who claim that neurovaccinia is a biological *modification of dermal vaccinia* (see p. 311).

VACCINIAL INFECTION OF MONKEYS

Numerous authors have studied the effects of vaccinia virus on monkeys (e g, Copeman, 1893–4 *a*, Sternberg and Reed, 1895, de Haan, 1896, Roger and Weil, 1902, Brinckerhoff and Tyzzer, 1906, Teissier, Duvoir, and Stevenin, 1911; Levaditi *et al.*, 1927, Aldershoff *et al*, 1929, Clearkin, 1929, 1930, Eckstein and Sarvan, 1930, Hurst and Fairbrother, 1930, Eckstein, 1931 *a, b*, 1932 *b*, 1933, Rivers, Sprunt, and Berry, 1933, Torres and Teixeria, 1934 *a*, Torres, 1935–6).

Rhesus, cynomolgus, cercopithecus, and cebus monkeys have been most commonly used, and the chimpanzee has also been shown to be susceptible.

Routes of Inoculation

Monkeys can be readily infected with vaccinia virus by application to the scarified skin, by intradermal inoculation, and by intracerebral injection (*vide infra*). Keratitis follows corneal inoculation Lesions are produced in the nasal, oral, and buccal mucosae after local application Apes can be infected by intratracheal and intrapulmonary injection (Eckstein, 1933).

After inoculation of the skin the animal usually develops a local vaccinial lesion after 3 to 4 days By the 5th day the eruption is raised, surrounded by an areola, shows a ring of vesicles, and is crusted centrally. By the 8th day the central crust has extended to cover some of the vesicles, subcutaneous edema is well developed. Sometimes a few "daughter" vesicles may appear. By 10 to 12 days the lesion has quite healed The animal may develop a slight temperature, the lymph nodes are enlarged Sometimes a generalized rash may occur.

Eckstein and Sarvan (1930) studied the effect of starvation on the development

ternal organs (except the liver) contained virus up to 24 hours after death but not after 48 hours.

Pathology

Skin. Copeman and Mann (1899) carried out a detailed study of the histological features of the skin after vaccination of the calf, and their results will now be quoted The earliest change is a preliminary dilatation of the intercellular lymph channels Thereafter, changes occur in the different layers of the epidermis as follows

After 48 hours, the basal cells have increased from 13 μ–15 μ to 30 μ–35 μ in length, and the nuclei from 10 μ to 13 5 μ Some cells, however, shrink owing to compression The remaining cells undergo reticulating or "ballooning" change The "balloons" are formed by the epithelium breaking up into a number of pillars surrounded by lymph, later, many of these are torn across, so as to form bullae These bullae separate the superficial epithelial cells from the deeper layers overlying the dermis The tension tears across intercellular bridges and cells are liberated in groups of 1 to 10 In the larger groups some cells appear to thrive, but the remainder show atrophic or reticulating change.

Guarnieri bodies are found in the epithelial cells from an early stage At first measuring only about 0 5 μ they soon increase up to 2 μ.

The cells in the deeper layers show a special tendency to undergo nuclear proliferation. This presents itself as follows Large cells are formed in which reticulation begins around the nucleus and spreads peripherally. The cell loses its definite contours and leukocytes enter. The original nucleus shrivels and becomes eosinophilic. These cells form one type of vaccinial giant cell Another type of giant cell is characterized by the condensation of its cell body due to absorption of fluid Daughter cells then form within the mother cell. These 2 types of giant cell develop at the height of the reaction (from the 2nd to 4th day) Another type, however, develops among healthy cells, mainly on the 4th and 5th days, it is represented by numerous vesicular nuclei free in a cavity between the surrounding cells

In the dermis the earliest change is evident 48 hours after vaccination, as a necrosis of the basal membrane which swells and becomes strongly eosinophilic This change occurs beneath the vaccinated area, even distant from the point where the epidermis is scarified. The reaction is noted at a time when the epithelial changes are only slight in extent Edema and leukocytic infiltration begin on the 2nd day and are maximal by the 5th Numerous free granules, probably leukocytic, are to be found in the lymph spaces

Cornea Tyzzer (1904) described the changes as follows Naked-eye, it is difficult to see lesions in the vaccinated cornea, but when placed in Zenker's fluid several minute rounded opacities appear (one may also use fluorescein). Two days after inoculation, many Guarnieri bodies may be found in certain areas After 5 days there are small foci of epithelial cells showing vacuolar degeneration changes

Nasal mucosa Tyzzer (1904) described the following changes in the nasal septum inoculated with vaccinia The vaccinated area becomes opaque and elevated, and extends slowly day by day After 5 days large vesicles are found in the epithelium, due to vacuolar degeneration of the epithelial cells, and numerous Guarnieri bodies occur

VACCINIAL INFECTION OF OTHER ANIMALS

Guinea-pigs

Vaccinia virus can be transmitted to guinea-pigs (Levaditi and Nicolau, 1923 *a*, Bedson and Bland, 1928, Bland, 1928 *b*, Grinker, 1930–1, Herrmann, 1931, Munsterer, 1934–5, Stritar and Hudson, 1936, Kroemer, 1938)

Bland (1928 *a*, *b*) studied the reaction of the scarified and epilated skin to inocu-

or repeated suboccipital puncture. The monkeys developed a diffuse encephalitis, and in some cases a meningo-encephalomyelitis.

(*h*) *Eckstein* (1932 *b*) was unable to produce involvement of the central nervous system in monkeys by injection of virus into the brachial plexus.

(*i*) *Pette and Kornyey* (1933) were not able to produce changes resembling those of human postvaccinal encephalitis by injection of dermal vaccinia into the carotids or the cisterna magna.

(*j*) *Rivers, Sprunt, and Berry* (1933) have carried out experiments in an attempt to produce encephalitis in monkeys (1) Following intracranial injection, a severe meningitis and a mild encephalitis developed, but there was no evidence of perivascular demyelination (2) The injection of virus intracranially in immune and partially immune monkeys did not produce a disseminated encephalomyelitis. (3) Similar injections with the addition of Duran-Reynals' testicular factor (*vide infra*) did not produce encephalomyelitis either.

(*k*) *Eckstein* (1933) found thromboses, hyperemia, and glial proliferation in the brain following intratracheal or intrapulmonary injection

Summary. Some difference of opinion is manifested in the above work It may, however, be concluded that the majority has found that meningitis is the characteristic lesion produced by the intracranial injection of vaccinia. Further, after intradermal injection, lesions do not usually develop in the brain

Distribution of Virus in Infected Monkeys

It appears that virus spreads fairly widely throughout the body after injection For instance, virus was isolated from the brain 8 to 10 days after dermal inoculation with neurovaccinia (Levaditi and Nicolau, 1926). McIntosh and Blaxall (*Report*, 1928) vaccinated a monkey in the skin and were able to isolate virus from the brain, liver, spleen, and blood on the 8th day Following intracerebral inoculation of monkeys with testicular virus, Hurst and Fairbrother (1930) found virus in the brain, lumbar cord, spleen, liver, kidney, lung, adrenal, testis, and ovary

VACCINIAL INFECTION OF BOVINES

Calves are most readily infected by application of virus to the scarified skin, and by *intradermal injection. Calves, of course, are the animals in which vaccine* lymph is most frequently passaged for use in human vaccination and this matter is fully discussed later in the section on vaccination (see Ch XXXIV).

Calves can be infected by other routes than the skin, however. After corneal scarification a well-marked keratitis develops in 6 to 7 days, infection can also be secured by injection into the anterior chamber (Straus, Chambon, and Ménard, 1890). Calves can be infected on the nasal mucosa (Tyzzer, 1904) Noguchi (*1915*) found that vaccinia could be passaged in young bulls by intratesticular injection

Chaumier (1924) reported that the subcutaneous inoculation of calves with vaccinia produced large infiltrated and edematous areas that gave a profuse yield of virus

Distribution of Virus

Virus may diffuse throughout the body of bovines after inoculation of the skin. For example, it may occur in the spleen, lymph glands, kidneys, and brain, just before death, in heifers inoculated intradermally (Barikine *et al*, 1924), Blaker (1936) isolated virus from the amniotic fluid of cows inoculated cutaneously McIntosh and Blaxall (*Report*, 1928) vaccinated calves on the skin and found virus in the blood, liver, and brain for about a fortnight Zeller *et al.* (1933) also studied the distribution of virus in the bodies of vaccinated calves It was isolated from the blood on the 6th and 7th days, but not in the first 4 days. Virus could be isolated from the flesh immediately after death, but not 24 hours later The in-

THE PRIMARY TISSUE REACTION IN EXPERIMENTAL VACCINIA

Much work has been carried out on the pathology of vaccinia, and considerable reference to such papers has already been made. It falls now to link up some of the above with work which has been carried out in other directions, with a view to studying the primary reaction of the tissues to vaccinia virus.

1. *Copeman and Mann* (1899) studied the histology of the skin of the vaccinated calf and found that necrotic swelling of the basal membrane is the primary change This is soon followed by swelling of the epidermal cells.

2. *Ledingham* (1924) carried out important studies in this connection From a study of the pathology of the skin and certain other tissues, he concluded that vaccinia has no epiblastic affinity (see also p 314). He regarded the vaccinial lesion as an acute infective granuloma in which the reticulo-endothelial system is predominantly involved.

3. *Watanabe* (1924), studying the histology of generalized vaccinial lesions, found no evidence of epidermal reaction, there being only inflammatory foci in the subepithelial tissue.

4 *Amies* (1938) carried out experiments in which he studied the reaction of the skin to inoculation of polydisperse and homogeneous suspensions of elementary bodies (see also p. 315). After inoculation of polydisperse suspensions (crude lapine) there is early and marked infiltration of both dermis and epidermis with inflammatory cells When homogeneous suspensions (washed elementary bodies) are used, the infiltration by inflammatory cells is much reduced, there is marked proliferation and "ballooning" of the malpighian cells, inclusions are a conspicuous feature. He believed that this change in the nature of the lesions is produced by a process of adaptation and selection, whereby the normal ectodermal activities of the virus are intensified.

5 *Widelock* (1938) studied the early changes in the skin after intracutaneous injection of vaccinia There is a correlation between the multiplication of the virus and the increase in the size and numbers of the epithelial cells. The earliest change is an increase in the size of the epithelial cells, later they increase also in numbers The increase in the total width of the epithelium is greatest when the virus attains its maximum multiplication. He considered that cellular infiltration of the epithelium occurs secondarily to the epithelial cell changes, which he regarded as primary.

In confirming work of Ledingham (1926 *b*), he showed that the injection of a mixture of India ink and virus prevents the formation of a typical vaccinial reaction, the virus, however, still multiplies and epithelium still undergoes proliferation.

6. *Observations in the egg* The infected chorio-allantoic membrane forms an ideal site for the study of the histological reaction to vaccinia Most workers have noted that the main reaction concerns the epithelial cells, Guarnieri body production often being an early feature (see p. 343) There is usually also considerable involvement of the mesoderm and, to a lesser extent, the endoderm Buddingh (1936 *a*) noted that a strain of neurotesticular virus had a particular predilection for the mesoderm

Levaditi and Voet (1937) have studied the action of both dermo- and neuroviruses on the chorio-allantois The first change, evident from the 18th hour onward, is an ectodermal thickening, these cells show numerous mitotic figures, are swollen, and contain both elementary and inclusion bodies. After 25 hours, inflammatory changes are seen in the mesoderm. From this time onward the ectoderm undergoes marked proliferation, and cell-nests form in the mesoderm From these studies they concluded that the vaccinia virus has a dominant epithelial affinity.

Conclusions It seems unwise to adopt too dogmatic an attitude with regard to the primary tissue reaction to vaccinia There is no doubt that the epidermal cells

lation of vaccinia; after the virus had been passaged for some generations, it acquired the property of producing pustular lesions. Injections may also be administered into the skin of the guinea-pig's pad.

After intracerebral injection of neurovaccinia, guinea-pigs die from meningo-encephalitis. There are mononuclear and polymorph cells in the meninges; the brain shows the changes of acute encephalitis, with inflammatory foci, and perivascular cuffing (Levaditi and Nicolau, 1923 *a*). Grinker (1930–1) stated that these animals can be infected by intracerebral injection of calf lymph, with the production, in some cases, of a meningo-encephalitis Olitsky and Long (1928), however, reported that neurovaccinia did not induce encephalitis in guinea-pigs on intracutaneous, intratesticular, corneal, or intracerebral injection.

Stritar and Hudson (1936) propagated virus by intracerebral injection of fetal guinea-pigs. Skin pocks were found, and necrotic areas in the lungs and kidneys

Mice

A number of authors has infected mice (Levaditi and Nicolau, 1923 *a*, Rosenau and Andervont, 1931; Buckup, 1935, Kanazawa, 1936; Eyer, 1937; Nelson, 1938, Bronson and Parker, 1941, 1944). They can be injected intracerebrally, when symptoms of encephalitis develop. Buckup (1935) found that strains of variola-vaccinia differed considerably in their powers of inducing meningo-encephalitis on intracerebral injection of white mice. Haagen (1934) found that by repeated brain passage a "fixed" strain could be produced, which caused death in 5 to 9 days. Mice can also be infected by application to the scarified skin, or by intraperitoneal, intravenous, or subcutaneous injection. Nelson (1938) found that after nasal instillation of culture virus, or dipping the nares in virus-containing liquid, the animals develop respiratory symptoms, and may die of pneumonia. The lungs show areas of consolidation, at first patchy, but later more confluent Histological examination shows necrosis of the bronchi, the alveolar walls are often necrotic, and the alveoli contain coagulated fluid and fibrin. Lister (1940) could not infect mice with Lister Institute lapinia.

Sheep

In certain institutes sheep are used to yield vaccine for human use, the virus being readily passed by dermal inoculation (Kasai, 1931)

Other Animals

Horses can be infected with vaccinia, and following intravenous injection generalized vaccinia may develop (Chauveau, 1865–6, 1877; also Raynaud, 1878).

Various authors have studied the vaccinial infection of the *chick* (Blanc and Caminopetros, 1923, Levaditi and Nicolau, 1923 *a*, Lowenthal *et al.*, 1925, Andervont, 1926 *a*, *b*, 1927, Findlay, 1927–8, Woodruff, 1930) Chickens can be infected by scarification of the comb or cornea, or cerebrally.

Chaumier (1924) reported that the subcutaneous inoculation of *asses* with vaccinia produces large infiltrated edematous areas that give a profuse yield of virus. [illegible] (Blaker, 1936) The *cat* can be infected cere- [illegible] [illegible] [illegible], especially on corneal inoculation (Findlay, 1927–8). After cutaneous inoculation with neurovaccinia a papulopustular eruption develops by the 4th day (Levaditi and Nicolau, 1923 *a*) Lesions can be produced on dermal inoculation, after treatment with thallium (Buschke *et al.*, 1931). It is also susceptible to intracerebral injection (Kubota, 1938).

The *ground squirrel* can be infected with vaccinia by corneal inoculation (Goschanskaja and Stschastny, 1933)

rabies did not develop, but, if vaccinia was injected shortly afterward, then rabies developed.

B. Poliomyelitis

Thompson (1930*a*) failed to adapt poliomyelitis virus to rabbits by admixture with vaccinia. Hurst and Fairbrother (1931) injected monkeys intracranially with a mixture of neurovaccinia and poliomyelitis virus. They did not find that the vaccinia modified the lesions of poliomyelitis, nor could it activate a weak strain of virus.

C. Foot-and-mouth Disease

Gildemeister and Helm (1932) recorded a definite antagonistic effect when mixtures of vaccinia and foot-and-mouth viruses were inoculated into guinea-pigs.

D. Herpes

A number of experiments has been carried out with herpes virus, because many used to believe that postvaccinal encephalitis was caused by the activation of this virus lying latent in the body, by the process of vaccination On the one hand, 2 groups of authors have adduced experimental evidence that vaccinia may have an activating effect on herpes virus Thus, when herpes virus was instilled intranasally, and at the same time neurovaccinia inoculated dermally, the animal often died from herpetic encephalitis (Levaditi and Nicolau, 1926) Further, Zurukzoglu *(1927) found that when either vaccine virus was injected intravenously, or herpes* subcutaneously, alone, then the rabbits lived. If the injections were combined the animals died from herpetic encephalitis On the other hand, the bulk of evidence appears to deny any activating role to vaccinia·

(*a*) For instance, in the *Report* of 1928, Gordon recorded the following experiments First, he inoculated rabbits intranasally with a nonencephalitogenic herpes strain, and simultaneously administered vaccinia nasally, or subcutaneously, no encephalitis developed. Secondly, he inoculated half a minimum lethal dose of

1. A sublethal dose of herpes was inoculated intracerebrally, 3 weeks later a cutaneous inoculation with vaccinia was performed
2. Neurovaccinia was inoculated nasally, and followed in 3 weeks by herpes intradermally
3. Herpes was administered nasally, and 3 weeks afterward a cutaneous inoculation with vaccinia was carried out
4. These procedures were, on occasions, followed by an intravenous injection of hexamine to endeavor to lower the blood-brain barrier, and to allow herpes to enter the central nervous system
5. Vaccinia (calf lymph) was inoculated cutaneously, and 5 days later herpes was *injected into the blood stream*

In none of these 5 experiments did any encephalitis result

(*c*) Perdrau (1928) studied the effect of inoculating a mixture of herpes and neurovaccinia intracerebrally in rabbits He found that a normal animal died in 2½ days, a rabbit immune to both viruses recovered, a rabbit immune to vaccinia died from herpetic encephalitis in 5 days, finally, a rabbit immune to herpes died in 5 days from vaccinia

(*d*) Berger (1929) inoculated rabbits on the cornea with herpes, *and later with* vaccinia, but no encephalitis developed

(*e*) Olitsky and Long (1928) could find no evidence that injections of neurovaccinia given corneally, by scarification, intratesticularly, or intracerebrally, stimu-

are often primarily and predominantly involved, but the other layers are not spared, and sometimes the mesodermal reaction in particular may be severe.

THE EFFECT OF CERTAIN BIOLOGICAL AGENTS ON THE VIRULENCE OF VACCINIA

Duran-Reynals's factor. Duran-Reynals (1929) reported that extracts of normal testis exalt the virulence of dermo- and neuro-viruses. The enhancing effect operates rather on the host cells than on the virus, for it was shown that after intravenous inoculation, virus localizes most readily in areas previously inoculated with testis extract. Moreover, enhanced lesions result if virus is inoculated into the skin up to 3 days after injection of extract. McClean (1930) showed that the intravenous injection of extract enhanced the lesions produced on intradermal inoculation About 25 per cent. of rabbits with enhanced lesions die from generalized vaccinia Kidney, brain, and liver extracts only show this enhancing power to a much less degree. The intradermal injection of fluid from embryo tissue and chicken sarcoma cultures secures the localization of intravenously injected virus; when virus is rendered almost inactive by the action of chloroform, potency can be restored by the addition of these agents, or of kieselguhr (Duran-Reynals, 1928 *a*).

[illegible] ct of testis extract should be made use [illegible] virus, the test material should be mix [illegible] experimental animals (Andersen, 1937 *a*). *Fellowes and Hudson (1939) have shown that the Duran-Reynals factor* occurs in both fetal and adult guinea-pig tissues.

Gastinel, Fasquelle, and Arnaud (1946) showed that there is no enhancement if the spreading factor and virus are inoculated together by scarification. On intradermal injection, the enhancing effect is noted slightly with dermal virus, but very markedly with neurovirus

Other enhancing substances Azoprotein solutions increase the size of dermal lesions (Claude, 1939), and a similar effect is secured by mucin (Clemmesen and Anderson, 1942) Sprunt (1942 *b*) concludes that if the interstitial fluid is decreased, *the lesions are more numerous, as virus is enabled to spread* Nontoxic rattlesnake venom exerts an enhancing effect (Duran-Reynals, 1939).

Gratia and Linz's (1931 a) phenomenon. These authors injected rabbits with testicular virus on the skin or intratesticularly, a day or so later a filtrate of a culture of *B coli* was administered intravenously A very severe hemorrhagic reaction followed in the inoculated testis, and in the lymph glands draining the site of dermal inoculation They also studied the effect of intracerebral injection of virus followed by *B coli* filtrate intravenously, some animals developed hemorrhages in the intestine, diaphragm, heart, lung, and lymph glands (Gratia and Linz, 1931 *b*)

Virulence-inhibiting effects Duran-Reynals and Stewart (1931) found that human sarcoma extracts inhibited vaccinial reactions Methionine and choline inhibit the dermal response (Sprunt, 1942 *a*), and a similar inhibition occurs in rabbits deprived of food (1942 *b*)

Rabbits inoculated with estrogenic hormones show an increased resistance, owing to increased tissue fluid and localization of the virus (Sprunt *et al*, 1938, Sprunt, 1941 *a*, *b*, *Taylor and Sprunt, 1943*)

SIMULTANEOUS INFECTION WITH VACCINIA AND OTHER VIRUSES

A. Rabies

Levaditi and Nicolau (1925) injected rabbits suffering from a latent neurovaccinial infection with street virus intracerebrally. Passage of brain tissue was carried out, at first rabies virus was demonstrable, but later vaccinia was found If rabies and vaccinia viruses were inoculated on the skin or cornea simultaneously,

rabies did not develop, but, if vaccinia was injected shortly afterward, then rabies developed.

B. Poliomyelitis

Thompson (1930 *a*) failed to adapt poliomyelitis virus to rabbits by admixture with vaccinia Hurst and Fairbrother (1931) injected monkeys intracranially with a mixture of neurovaccinia and poliomyelitis virus They did not find that the vaccinia modified the lesions of poliomyelitis, nor could it activate a weak strain of virus

C. Foot-and-mouth Disease

Gildemeister and Helm (1932) recorded a definite antagonistic effect when mixtures of vaccinia and foot-and-mouth viruses were inoculated into guinea-pigs

D. Herpes

A number of experiments has been carried out with herpes virus, because many used to believe that postvaccinal encephalitis was caused by the activation of this virus lying latent in the body, by the process of vaccination On the one hand, 2 groups of authors have adduced experimental evidence that vaccinia may have an activating effect on herpes virus Thus, when herpes virus was instilled intranasally, and at the same time neurovaccinia inoculated dermally, the animal often died from herpetic encephalitis (Levaditi and Nicolau, 1926). Further, Zurukzoglu (1927) found that when either vaccine virus was injected intravenously, or herpes subcutaneously, alone, then the rabbits lived. If the injections were combined the animals died from herpetic encephalitis On the other hand, the bulk of evidence appears to deny any activating role to vaccinia

(*a*) For instance, in the *Report* of 1928, Gordon recorded the following experiments First, he inoculated rabbits intranasally with a nonencephalitogenic herpes strain, and simultaneously administered vaccinia nasally, or subcutaneously,

minimum lethal dose of

vaccine lymph cutane-

its directed to the same

1. A sublethal dose of herpes was inoculated intracerebrally, 3 weeks later a cutaneous inoculation with vaccinia was performed
2. Neurovaccinia was inoculated nasally, and followed in 3 weeks by herpes intradermally.
3. Herpes was administered nasally, and 3 weeks afterward a cutaneous inoculation with vaccinia was carried out.
4. These procedures were, on occasions, followed by an intravenous injection of hexamine to endeavor to lower the blood-brain barrier, and to allow herpes to enter the central nervous system
5. Vaccinia (calf lymph) was inoculated cutaneously, and 5 days later herpes was injected into the blood stream

In none of these 5 experiments did any encephalitis result

(*c*) Perdrau (1928) studied the effect of inoculating a mixture of herpes and neurovaccinia intracerebrally in rabbits He found that a normal animal died in 2½ days, a rabbit immune to both viruses recovered, a rabbit immune to vaccinia died from herpetic encephalitis in 5 days, finally, a rabbit immune to herpes died in 5 days from vaccinia

(*d*) Berger (1929) inoculated rabbits on the cornea with herpes, and later with

lated Levaditi's C strain of herpes to produce encephalitis on intracerebral injection.

(*f*) *The cytoplasmic inclusions of vaccinia and the nuclear inclusions of B virus* or herpes virus have been found in single cells of the rabbit cornea inoculated with mixtures (Syverton and Berry, 1947 *b*).

RELATIONSHIP OF VACCINIA TO CERTAIN OTHER VIRUSES

A. Foot-and-mouth Disease

Uhlenhuth and Trautwein (1934–5) were not able to render guinea-pigs resistant to vaccinia virus by injections of foot-and-mouth virus (all 3 types were used). Conversely, injections of vaccinia did not protect the animals against foot-and-mouth disease.

B. Herpes Febrilis

Zurukzoglu (1927) claimed that vaccinial infection gave rise to some immunity to herpes, and vice versa. Gildemeister and Herzberg (1925) also claimed a relationship between herpes and vaccinia on the basis of cross immunity tests carried out *in vivo* and *in vitro*. Later (1927) they found that the majority of variola-immune rabbits only developed mild reactions on injection of herpes Many workers, however, have shown that there is no immunological relationship (Bedson and Bland, 1928, Perdrau, see *Report*, 1928; Keller and Schaefer, 1929, Gildemeister and Ahlfeld, 1937; Kanazawa, 1938).

C. Fowl-pox

Although Toyoda (1924) and Pandit (1926–7) claimed that fowl-pox could be converted into a virus resembling vaccinia by passage through experimental animals, it is not generally believed that the viruses of fowl-pox and vaccinia are related. Andervont (1926 *b*) could not demonstrate any resistance to fowl-pox in vaccinia-immune birds, nor was vaccinia-immune serum virucidal for fowl-pox virus Ledingham (1926 *a*) was unable to demonstrate any cross immunity Findlay (1927–8) and Woodruff (1930) were likewise unable to find any relationship.

D. Ectromelia

Vaccinia and ectromelia have similar hemagglutinating properties (see Ch XXXI) Specific antisera show some cross neutralization in the CCA-inhibition test, and immunized rabbits and mice show some degree of cross resistance It is considered probable that the 2 agents have a similar biological origin, and that ectromelia is a member of the animal pock disease group (Burnet and Boake, 1946)

CERTAIN MISCELLANEOUS EXPERIMENTS WITH VACCINIA

Pearce (1928 *a, b, c*) studied the effect of simultaneous infection with vaccinia and syphilis in rabbits, with the following results If vaccinia was injected intracutaneously, and at the same time *Treponema pallidum* intratesticularly or intradermally, then the syphilitic reaction was extremely severe A similar modification occurred if rabbits were injected intratesticularly with the 2 agents If the animal injected with *Treponema pallidum* was immune to vaccinia, this had the effect of causing the resultant syphilitic infection to be very mild.

It has been claimed that the injection of calf lymph or neurotropic virus cerebrally in mice has some protective effect against death from the cerebral injection of *H pertussis* at a later date (Dalldorf, Cohen, and Coffey, 1947)

Neurovaccinia survives if injected into epitheliomata, but not sarcomata, of rats and mice, if the injection is intravenous, virus localizes in epitheliomata, but not sarcomata (Levaditi and Nicolau, 1923 *b*). These workers also studied the immunity reactions of vaccinial infection of tumors, epitheliomata growing in a vac-

cinia-immune animal participated in the general refractory state, but if this tumor was grafted to a susceptible host it was no longer refractory to injection of virus

Rivers and Pearce (1925) studied the effect of inoculating a transplantable rabbit tumor with vaccinia. It was found that the virus survived in the tumor for at least 64 days, and was carried on when the tumor was passaged. The animals bearing these tumors infected with virus became immune to vaccinia, but this did not destroy the virus

Levaditi and Schoen (1936) inoculated rabbits bearing Shope's papillomata with neurovaccinia either intravenously, intradermally, or into the tumor itself. On the 5th day virus was found in the tumor in every case. Syverton and Berry also found that these papillomata could be infected by vaccinia (1947 *a*).

with vaccinia when in-

12 days and can cause

CHAPTER XXIX

THE VARIOLA-VACCINIA VIRUS: ELEMENTARY AND INCLUSION BODIES

1. THE ELEMENTARY BODIES OF VARIOLA-VACCINIA

For many years it has been known that small granules can be demonstrated in various suspensions prepared from tissues infected with vaccinia. Although the credit of discovering these bodies is usually given to Paschen (1906)[1] they were actually discovered many years earlier by Buist (1886) in Edinburgh (see Gordon, 1937, Mackie and van Rooyen, 1937). These bodies are known variously as elementary bodies, EBs, and Paschen bodies, although it would seem to be more accurate to call them Buist bodies. Mackie and van Rooyen have proposed the term *Buistia pascheni*, thereby commemorating the work of both Buist and Paschen Various other names have been proposed too for instance, Aragão (1933) suggested that the name *Chlamydozoa ribasi* be applied to the elementary bodies of alastrim, and von Prowazek employed the term *Chlamydozoa variolae*. Goodpasture (1933) introduced the designation *Borreliota variolae hominis* to describe the elementary bodies of smallpox, and *Borreliota variolae bovis* for those of vaccinia.

So many authors have described the occurrence of elementary bodies in vaccinial, alastrinic, and variolar lesions of man and animals that only comparatively few can be mentioned by name (von Prowazek and Aragão, 1909, Aragão, 1911, MacCallum and Oppenheimer, 1922, Craciun and Oppenheimer, 1926, Mudd and Nakajima, 1929–30, Eagles and Ledingham, 1932; Goschanskaja and Skrotzky, 1932, Paschen, 1933–4, Taniguchi *et al*, 1932 *a*, *b*, 1933, 1934, Craigie, 1933, Haagen and Kodama, 1934, Eagles, 1935 *a*, Haagen, 1935, Parker and Rivers, 1935, Turevich, 1935, Kanazawa, 1936) Smadel and Hoagland (1942) have published a general review on the properties of vaccinial EB's

Morphology and Size of Elementary Bodies

The elementary bodies of vaccinia or variola can be demonstrated microscopically in films stained by Paschen's or other method, as small granules, sometimes occurring in pairs, short chains, or clusters (see Figs. 4 and 5) It appears from experimental observations that elementary bodies enter cells and proliferate to form inclusion (Guarnieri) bodies. Examination of these inclusion bodies shows that they are, at any rate partly, composed of elementary-body-like granules

The size of elementary bodies can be estimated by various direct micrometric methods (see Ch I), when they are found to measure approximately 0 2 μ in diameter Of recent years, more accurate methods have been introduced, following certain earlier experiments by Yaoi and Kasai (1929 *e*) By ultrafiltration for example, the following results have been obtained 0 125 μ to 0 175 μ (Elford and Andrewes, 1932), 0 14 μ to 0 16 μ (Levaditi, Paic, and Krassnoff, 1936, see also Paic *et al*, 1938)

Ultracentrifugation studies have also been used to determine the size of vaccinial elementary bodies (Bechhold and Schlesinger, 1931, Elford and Andrewes, 1936, Gratia and Plotz, 1938, Pickels and Smadel, 1938) The following results have been obtained 0 17 to 0 18 μ (Elford and Andrewes), 0 21 to 0 23 μ (Bechhold and Schlesinger), 0 236 μ (Pickels and Smadel)

[1] References are appended at the conclusion of Ch XXXV, p 403 et seq

Elementary bodies give a negative reaction in Feulgen's test (Haagen, 1937 *b*, Robinow and Bland, 1938).

Electron micrographs show vaccinial EB's to be brick-shaped, with areas of electronic density, there appears to be a limiting membrane (Greene, Anderson, and Smadel, 1942; Smadel, Anderson, and Green, 1942, Groupé, Oskay, and Rake, 1946, Sharp *et al.*, 1946, Dawson and McFarlane, 1948, Ruska and Kausche, 1943, see also Fig. 29A). Nagler and Rake (1948) estimate the size at 244 × 302 m μ.

The Sites of Occurrence of Elementary Bodies

Paschen bodies have been found in all types of vaccinial infection, and in cases of variola and alastrim The sites in which they can be demonstrated most readily are as follows. in human vaccinia, variola, or alastrim vesicle fluid, in vaccinial dermal pulp obtained from calves, rabbits, and other animals, in testicular suspensions of infected rabbits, in exudate after nasal instillation of mice (Nelson, 1938). Certain investigators have demonstrated the occurrence of elementary bodies in stained smears of infected tissue cultures (Haagen, 1931, Nauck and Paschen, 1932 *a*, *b*, Taniguchi *et al*, 1933, Haagen and Kodama, 1934, Togounova, 1935, *et al*, 1935, Nauck and Robinow, 1935–6). Elementary bodies can be demonstrated very readily by suitable staining in smears of infected chorio-allantoic membranes (Goodpasture *et al*, 1932, 1935, Nauck and Paschen, 1933, Goodpasture and Buddingh, 1934, Peragallo, 1936–7, Lazarus *et al*, 1937, Stevenson and Butler, 1939).

The Preparation of Elementary Body Suspensions

Following certain earlier experiments (MacCallum and Oppenheimer, 1922, Craciun and Oppenheimer, 1926), it is now possible to obtain EB suspensions freed almost completely from extraneous material. Satisfactory EB preparations can be obtained only by using active, recently passed, material as seed (Beard *et al*, 1937, Amies, 1938). Many methods have been used for making suspensions of vaccinial EB's, for example

1 *Craigie's method* is described in Ch XI

2. *Smadel and Wall's (1937) method* Up to 25 chorio-allantoic membranes are rinsed in Locke's solution They are then dropped singly into ethyl ether, mixed in Locke's solution, and ground, 10–20 c c of dilute buffer (pH 7 2) is added, and the suspension shaken The sediment is deposited at 1,000 r.p m , resuspended in buffer and recentrifuged Both supernatants are pooled and spun at 1,000 r p m for 10 minutes The supernatant is then run in the Swedish angle centrifuge for 1 hour at 3,500 r p m The sediment, which contains the EB's as well as debris, is taken up in 5–10 c c. buffer (pH 8 0), and 0 5 c c filtered 1 per cent commercial trypsin (freed from lipoids by extraction with ether) is added The mixture is incubated at 37° C for ½ to 1 hour The digested material is then washed 3–7 times, using the angle centrifuge After the final washing, the suspension is spun in the horizontal centrifuge for ½ hour at 2,500 r p m to remove particles larger than the EB's Levaditi and Giuntini (1940) and McIntosh and Selbie (1940) have also used trypsin

3 *Henderson and McClean (1939)* used the method introduced by *Behrens and Nielsen (1935)*. Ground vaccine pulp is made ... ing, coarse tissue particles are remov... precipitated with citric acid, or dialyz... performed at 2,000 r p m for ½ hou... sodium carbonate, and 0 43 per cent NaCl and 1 per cent Difco proteose peptone are added These preparations can be kept for many weeks To keep for prolonged periods, filter the supernatant through Berkefeld V and Gradocol filters, desiccate from the frozen state in 1 c c amounts in ampules, and seal in nitrogen

4 *Ledingham's (1931) method* Early material from the skin is thoroughly triturated in a mortar with distilled water The crude suspension is then shaken up in a flask with at least an equal volume of ether and allowed to stand on the bench for at least 24 hours, being frequently shaken up during this period The suspension is then centrifuged at high

speed. The upper layer of ether, and the large middle layer of light fatty matter which rises to the surface are removed, leaving an underlying opalescent fluid. This underlying layer, together with the deposit, is again centrifuged at high speed for at least 1 hour (9,000 r.p.m.). The resulting deposit is collected after discarding the supernatant. This small deposit, consisting of EB's and cell debris is suspended in formol saline (1/400). By further fractional centrifugation, it is possible to eliminate practically all grosser debris, leaving EB's only.

The Infectivity of Elementary Bodies

It can be shown readily that the infectivity of vaccinia virus is intimately connected with the elementary bodies. For instance, if suspensions of elementary bodies are centrifuged, tests show infectivity to be associated with the elementary body deposit, and the supernatant fluid to be noninfective (Eagles and Ledingham, 1932). Vaccinial infection can be transmitted in series by means of washed elementary bodies (Craigie, 1933). When suspensions are passed through a Seitz filter, the material which remains behind on the disk contains the elementary bodies. By suitable washing and centrifuging, it can be shown that a suspension of the elementary bodies has a similar virus content to that of the original extract (Craigie, 1932 *a*).

Certain methods have been described whereby the numbers of elementary bodies in any fluid may be estimated. Such studies have usually been concerned with associating the number of elementary bodies with the degree of infectivity of the fluid containing them. Parker and Rivers (1936 *b*), for instance, have worked in this connection. They found that elementary bodies actually could be counted, by replicate counts, using a Petroff-Hauser chamber. Further, they found that the elementary body content of a suspension could be determined by using Gates's densitometer. They attempted to correlate the numbers of elementary bodies and infective units in any given suspension. Rabbits were infected with virus intradermally and the end point of the titration was taken as the dilution of virus which would lead, theoretically, to an equal number of positive and negative results. Using these methods, Parker and Rivers found that there was a direct correlation between the numbers of elementary bodies and the number of infective units in any given suspension.

Parker (1938 *b*) has described a method whereby the number of virus particles needed to cause infection of the rabbit's skin can be estimated. Intradermal injections of diluted suspensions of virus are made in rabbits. The percentage of inoculations of each dilution giving lesions is then noted, and statistical analysis applied. Parker studied various strains of virus by this means, and found that infection followed inoculation of a single particle of the New York City Board of Health strain, of a tissue culture derivative of this strain, and of the Noguchi strain. However, the tissue culture strain produced a very much less severe reaction than did the New York strain. He concluded, therefore, that factors other than pure infectivity must be responsible for the different reactions observed.

A number of later workers has investigated this problem, and their work serves to emphasize the complexity of the position. It appears that though theoretically certain strains may be so infective that a single EB can cause infection, in practice a minimal infective dose usually contains several EB's. Estimates of the number of EB's per minimal infective dose have been made, for example 4.2 was the average figure obtained by Smadel, Rivers, and Pickels (1939). Sprunt, Marx, and Beard (1940) found that an average of 366 bodies behaved as an infectious unit. They agreed that under ideal conditions a single EB might behave as an infective unit. The frequency of positive and negative results on the rabbit skin followed the curve to be expected if a single EB is infective. Discrepancy was dependent on the experimental conditions with respect to the strain of EB, the volume of the inoculum, and the variation in host susceptibility.

Levaditi and his coworkers have published many papers on this subject. They worked chiefly with EB suspensions prepared from chorio-allantoic membranes by trypsinization and centrifugation They counted the number of EB's by fluorescence microscopy in a counting chamber, and determined the number of EB's per minimal infective dose, usually by intradermal or cerebral injection in rabbits (Levaditi, 1939 *a, b, c*, 1941 *a*, Levaditi *et al*, 1939 *a, c*, 1940 *a, b*, Lépine, Levaditi, and Giuntini, 1944). They estimated the number of EB's of neurovaccinia in a minimal infective dose, as shown by cerebral titration, as between 21 and 390 (1939 *c*). They also showed that if numbers of elementary bodies too few to produce a macroscopic lesion in the skin were injected, multiple microscopic foci could be found, strongly suggesting that the minimal infective dose judged by naked eye examination contains many EB's (Levaditi *et al*, 1940 *a*)

The main factors that determine the infectivity of EB suspensions may be summarized as follows·

1. The EB is probably possessed of an inherent virulence depending on the strain. Parker, Bronson, and Green (1941) titrated 8 different strains of vaccinia in various animals They concluded that in a virus of maximum virulence an infectious unit was present in a single EB, but in strains of lower virulence the infectious unit contained many EB's.

2. The source of the suspension is of importance. For example, the number of EB's needed to produce a dermal lesion is much smaller if the suspension has been prepared from the chorio-allantois rather than the skin (Levaditi *et al*, 1940 *a*, Levaditi and Reinié, 1939 *a*).

3. The number of infectious units found in a given suspension depends chiefly on the concentration of EB's and not on the total volume. Smaller inocula are relatively more effective than larger (Sprunt, 1939, 1941 *a*).

4 The species of animal used for the test inoculation is of importance, rabbits, for example, being more sensitive than monkeys (Levaditi *et al*, 1940 *a*) Different results will be obtained according to whether the inoculation is made cerebrally or dermally (Levaditi and Reinié, 1939 *a*).

5 The question of variation in the susceptibility of the host is fundamental (Bryan and Beard, 1940 *a, b*, Sprunt and McDerman, 1940, Sprunt, Marx, and
B ways, e g, by giving estro-
g the amount of intercellular
fl (1941 *a*) concluded that in
addition
number
of host c
virus, e
of a lesion Spreading virus over a larger area increases the probability of a lesion The ratio of virus particles to host cells partly determines whether a lesion occurs.

Immunological Reactions of Elementary Bodies

This question is fully discussed in the chapter on the immunological reactions of variola-vaccinia virus (Ch. XXXIII), but here it may be said that elementary

standing

Chemical Composition of Elementary Bodies

It has been found that washed elementary bodies contain ash, carbohydrate, lipoid, fat, and nitrogen (Hughes, Parker, and Rivers, 1935, Moriyama 1937 *b, c, d;* Moriyama and Ohashi, 1939).

Hoagland, Smadel, and Rivers (1940) gave the following figures total nitrogen, 15.3 per cent., total carbon, 33.7 per cent., total phosphorus, 0 57 per cent.; cholesterol, 1.4 per cent.; phospholipoid 2.2 per cent.; neutral fat, 2 2 per cent, reducing sugars after hydrolysis, 2.8 per cent.; cystine, 1 9 per cent

Nucleic acid has been found, mostly consisting of the thymus type (Hoagland *et al*, 1940 *a*, Smadel, Lavin, and Dubos, 1940). Biotin has been demonstrated (Hoagland *et al.*, 1940 *c*), also copper (Hoagland *et al.*, 1941 *a*).

The fluorescence exhibited by purified EB's in UVL is due to flavin-adenine-dinucleotide (Hoagland *et al*, 1941 *b*).

EB's contain a lipoid material probably derived from the host, and adsorbed onto the virus, after extraction with ether or benzene, infectivity is unimpaired (McFarlane and Macfarlane, 1939, McFarlane *et al*, 1939). The virus particle has large amounts (7–8 volumes) of water associated with it in the form of an atmosphere (McFarlane *et al.*, 1939).

Metabolism of Elementary Bodies

Breinl and G'owazky (1935) found that there was evidence of metabolism in aerobic tests, but that this was very feeble in anaerobic tests Parker and Smythe (1937) found that the quantities of oxygen consumed, and acid liberated, were very small, further, the great part of the gaseous exchange took place during the first hour of test There was no increased absorption of oxygen on addition of glucose The virus was found to be perfectly active at the end of the experiment. They maintained that the results were compatible with a survival, but not with growth, of virus.

EB suspensions show phosphatase, catalase, and lipase activity (Macfarlane and Salaman, 1938, Hoagland *et al*, 1942) Suspensions show no dehydrogenase activity toward a number of substrates (Macfarlane and Salaman, 1938) In later work, it was shown that suspensions lacked zymohexase, enolase, α and β glucosidases, and nucleosidase, they hydrolyzed ribonucleic acid (Macfarlane and Dolby, 1940)

The Reaction of Elementary Bodies to Physical and Chemical Agents

The influence of reaction has been studied (Beard *et al*, 1937, 1938, Moriyama, 1937 *b*). Infectivity is rapidly lost at pH4 and 10, but is stable in between. The isoelectric point is 4 3–4 6

Sonic and supersonic waves do not appear to disrupt EB's (Rivers, Smadel, and Chambers, 1937; Hopwood, Salaman, and McFarlane, 1939).

X-rays cause inactivation (Gowen and Lucas, 1939) Lea and Salaman (1942), using alpha, x-, and gamma rays found that the virus could be inactivated by a single ionization They calculated that the radiosensitive material represents an area of about ¼ of the cross sectional area of the EB, but only 1/200 of its volume The radiosensitive targets, they suggested, may be genes Bonet-Maury (1941) and Bonet-Maury and Pérault (1941) have studied the action of the alpha rays of radon Irradiation with *ultraviolet light* destroys virus in suspensions or atomized form (Giuntini and Reimé, 1939, Levaditi *et al.*, 1939 *b*, Giuntini, 1941, Edward, Lush, and Bourdillon, 1943)

As regards *storage*, EB's can be maintained in an infective condition by desiccating *in vacuo* from the frozen state Even in broth they retain activity for considerable periods (Amies, 1934 *a*) Suspensions are rendered more stable by the addition of 0 1 per cent gelatin or 1 per cent peptone (Behrens and Ferguson, 1935)

Various *chemicals* inactivate EB's, e g, formol (Craigie and Wishart, 1933), 50 per cent or 75 per cent ethyl alcohol or acetone inactivate EB's in 3 hours at 14° C. (McClean, 1945) Pepsin and papain cause solution, with the release of amino nitrogen, crystalline trypsin and certain other enzymes are without effect (Hoagland *et al.*, 1940 *b*).

Certain Physical Properties

The density of EB's lies between 1.12 and 1.18 (MacCallum and Oppenheimer, 1922; Elford and Andrewes, 1936, McFarlane, 1938, Smadel *et al*, 1938, Moriyama and Ohashi, 1939). The weight of a single EB has been estimated at 5.2 to 5.34 $\times 10^{-15}$ gm (Smadel, Rivers, and Pickels, 1939, McIntosh and Selbie, 1940)

Virus can be aerosolized and recovered from the atmosphere (by exposure of the chorio-allantois) as late as the 8th hour after spraying (Buchbinder and Solotorovsky, 1941).

2. THE INCLUSION BODIES OF VARIOLA-VACCINIA

The large eosinophilic inclusion bodies of variola-vaccinia are among the best known of all inclusions, and are held to be quite specific Although it is possible that these bodies may have been described by Weigert in 1874 and by Pfeiffer in 1887, the main credit goes to Guarnieri (1892, 1894 *a*, *b*, 1897), the inclusions being universally known by his name. Although demonstrable in human tissue from cases of smallpox, Guarnieri bodies have been most studied in experimental animals, particularly in the rabbit's cornea, and more recently in infected eggs and tissue cultures

A very large number of authors has confirmed Guarnieri's original findings, and certain of these may be specially mentioned (Babès, 1894, Clarke, 1894, 1895, Monti, 1894 *a*, *b*, Pfeiffer, 1894, 1895, Ruffer, 1894, Ruffer and Plimmer, 1894, von

The Morphology and Occurrence of Guarnieri Bodies

Fully developed Guarnieri bodies are comparatively large (up to 10 μ), and usually circular or ovoid structures While the inclusions of vaccinia and variola are usually eosinophilic, those of alastrim are basophilic, these and certain other differential features are more fully described below Although usually homogeneous, Guarnieri bodies may appear definitely granular even in ordinary stained films, and by special modern methods of examination it has been shown that Guarnieri bodies are probably composed of masses of elementary bodies held together in a matrix They may be single or multiple, and are often surrounded by an unstained halo They are usually found in the perinuclear space.

Guarnieri bodies can be demonstrated in all types of infection with the variola-vaccinia virus, both in human and animal tissues They have been demonstrated in the epithelial cells of the skin, cornea, nose, mouth, larynx, pharynx, esophagus, sebaceous and meibomian glands, and conjunctiva, in the columnar cells of the nose, trachea, testes, and seminal vesicles, in the alveoli of the lung, in endothelial cells of vessels, connective tissue cells, and fibroblasts in infected tissue cultures and chorio-allantoic membranes

Intranuclear Inclusions

Intranuclear inclusion bodies occur most typically in variola, to a lesser extent in alastrim, but not in vaccinia, their characters have been described by Torres (1935–6) as follows

(*a*) Cytoplasmic and nuclear inclusions are not found in the same cell

(*b*) The cells with nuclear inclusions are found mainly at the bottom of the

vesicle, while those with cytoplasmic bodies are more numerous in the cells of the middle part of the malpighian layer.

(c) The intranuclear inclusions of variola may have various forms First, there may be an irregular mass (or small masses) of varying size which appears acidophilic; the nuclear membrane is little altered. Second, the inclusion may fill the whole nucleoplasm and be separated from the membrane by a clear space. Third, the inclusion may be formed by one or more regular ovoid or spherical acidophilic bodies.

Brinckerhoff and Tyzzer (1906) reported that the intranuclear forms occur only in small numbers in the primary skin lesions of inoculated monkeys, but in far greater numbers in the orang-utan. They reported also that nuclear forms are found only occasionally in the generalized lesions developing after dermal inoculation of the monkey with variola. They are, however, numerous in the eruptions which follow intravenous inoculation.

Comparisons between Inclusions of Alastrim and Variola

The South American workers, Torres and Teixeria, have paid particular attention to certain morphological differences between the inclusions of alastrim, variola, and vaccinia (Torres and Teixeria, 1933 *a–d*, 1934 *a, b*, 1935 *a, b*, 1937, Torres, 1935–6). Many of these observations have been carried out in monkeys.

(*a*) The inclusions of alastrim stain pale blue with safranine, but those of variola are red.

(*b*) The alastrim body is usually basophilic with HE, whereas the variola-vaccinia bodies are eosinophilic or polychromatophilic.

(*c*) In the later stages of infection, the alastrim body is usually single, or at most in pairs, whereas the other bodies are often multiple.

(*d*) The single inclusions of alastrim are larger than those of variola.

(*e*) The alastrim bodies never occupy an excavation in the nucleus, whereas this often occurs with variola.

(*f*) In the vesicle or pustule stage, the alastrim bodies are very scanty and best seen in the floor or walls, but in variola they are very numerous, and are seen best in the walls of the lesion.

(*g*) *Intranuclear inclusions of variola are acidophilic*, round or oval, and are separated by a halo from the membrane; they are single or multiple (up to 4) The inclusions of alastrim are retiform, and lack the definite structure of those of variola. Intranuclear inclusions do not occur in vaccinia.

(*h*) The nuclear membrane is considerably thickened in variola, whereas only moderately in alastrim The nucleus itself is diminished in variola, but increased in alastrim

Alleged Production of Guarnieri Bodies by Nonspecific Means

Certain authors claim to have produced Guarnieri-like structures by nonspecific means, e g, inoculation of croton oil, iodine, and other irritants (Ferroni and Massari, 1893), and inoculation of cultures of *B coli* or *B. paratyphosus* A (Pot, 1930). The specific origin of Guarnieri bodies is, however, unquestionable, and it has been shown that they cannot be produced by the inoculation of chemical irritants, diphtheria or tetanus toxins, or bacterial cultures (Rhodes and van Rooyen, 1937 *a*, Squarcia, 1938)

The Biological Nature of Guarnieri Bodies

1. The protozoal theory.

That Guarnieri bodies are forms of a protozoal parasite was widely believed at one time Guarnieri, for example, applied the term *Cytoryctes variolae* to the

FIG 29A Electron microscope photograph of elementary Paschen bodies of vaccinia, shadowcast with chromium, × 25,000

bodies, under the impression that they were protozoal and possessed of a nucleus Calkins (1904) described a complicated life cycle. Magrath and Brinckerhoff (1904 *a*) also postulated a protozoal life cycle (see also Brinckerhoff, 1904; Tyzzer, 1904)

2. The possible rôle of nuclei and nucleoli.

Certain authors suggested that Guarnieri bodies are composed of extruded nucleoli (Hammerschmidt, 1919, Ludford, 1927–8) It was also suggested that Guarnieri bodies may be nuclear fragments (Babès, 1894, Salmon, 1897). Eberbeck (1929) believed that Guarnieri bodies are derived from nuclei, nucleoli, and chromatin particles

That Guarnieri bodies contain chromatin appeared unlikely from the work of Cowdry (1922), who found that they do not give a positive Bensley-MacCallum test for iron However, more recently the nuclear theory has received support from Milovidov (1933–4) who has found that Guarnieri bodies give a positive nuclear reaction for thymonucleic acid (Feulgen test)

Others have also found that the Guarnieri body gives a positive Feulgen test, but do not thereby believe that the inclusion is necessarily composed of nuclear material (Haagen, 1937 *b*, Haagen and Kodama, 1937, Robinow and Bland, 1938, Bland and Robinow, 1939)

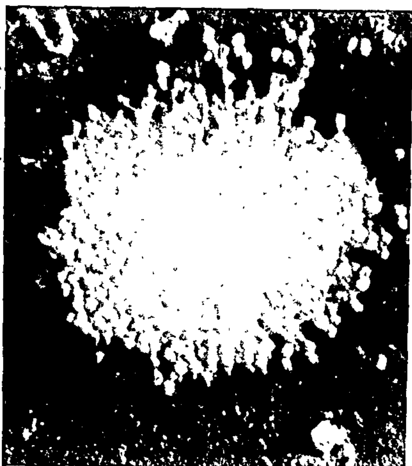

FIG 29B Electron microscope photograph prepared from smallpox vesicle fluid provided by *Dr E S Horgan of Khartoum*, showing Guarnieri inclusion body Shadowcast with chromium, × 8,000

3. The rôle of phagocyted red cells.

Woodcock (1921) suggested that Guarnieri bodies are phagocyted erythrocytes

4. Paschen's (1932) views.

Paschen holds that no single explanation can account for the Guarnieri body, and offers the following alternatives

(*a*) Guarnieri bodies are phagocyted leukocytes, sometimes perhaps a whole leukocyte, or a large part of it, is engulfed, at other times it is only the pyknotic nucleus

(*b*) Nucleolar extrusion occurs and gives rise to Guarnieri bodies

(*c*) Extrusion of chromatin takes place from the nucleus into the cytoplasm

(*d*) The cytoplasmic bodies are formed of a chromatin and a plastin component Probably vaccinia exerts a "toxic" effect which causes the normally united chromatin and plastin to dissociate and gives rise to inclusions (see also Nauck and Paschen, 1932 *a*)

(*e*) The small granular types of structure are probably true virus colonies

5. The rôle of other cellular constituents.

Cowdry (1922) found that Guarnieri bodies do not stain with Janus green for mitochondria, and that the result of silver preparations makes it unlikely that they

are constituted by the Golgi apparatus Ludford (1927–8), however, carried out a study of vaccinial inclusions in the skin of the chick and arrived at somewhat different conclusions He found that they arise as minute granules, which increase in size and become vesicular. The vesicles become covered with a strongly osmophilic substance He stated that the bodies are intimately associated with the Golgi apparatus in their early stages of development.

6. The Guarnieri body as a virus colony.

von Prowazek and his coworkers held that small elementary bodies enter the cell, where they increase in size to become initial bodies. These bodies measure up to 4 μ in diameter, and may divide up into elementary bodies again, or may become surrounded with a covering of reactionary material (chromatin and plastin) derived from the cell, thus constituting Guarnieri bodies (von Prowazek, 1905 *a*, *b*, 1910, 1912, von Prowazek and Aragão, 1908, 1909, von Prowazek and Miyaji, 1914, von Prowazek and Yamamoto, 1909). Hallenberger (1918) also supported these views He regarded the Guarnieri body as a defensive structure inclosing the virus particles, the virus initial body being covered with chromatin and plastin layers

For many years authors have realized that cells infected with vaccinia virus

og-

–5,

ted

some time ago that the Guarnieri body is a product of the virus itself, that is to say, an intracellular colony (Ungermann and Zuelzer, 1920, Gins, 1922).

Now it will be recalled that the inclusions of mouse ectromelia and fowl-pox have been shown to be infective, and to contain a mass of elementary bodies The inclusions of molluscum contagiosum and psittacosis likewise contain countless elementary bodies Naturally one is led to inquire whether the Guarnieri body too consists of a colony of elementary bodies. Modern work with infected tissue cultures and chorio-allantoic membranes has shown quite definitely that such is the case, and the most important observations will now be cited in detail

(*a*) *Goodpasture* et al (1932), working with the infected chorio-allantoic membrane of the fertile hen's egg, found that inclusions developed in ectodermal cells before there was any evidence of cellular infiltration Almost all these cells in the recently infected areas showed inclusions, which were granular and amorphous, and sometimes occurred in irregular clumps When single inclusions were present, they were often triangular, with the base of the triangle toward the nucleus. Similar

(*b*) *Tang and Wei* (1937), by microscopical examination of chorio-allantoic lesions in the fresh state (with or without cresyl blue or neutral red), noted the occurrence of granular bodies in cells at the periphery of the pocks These structures were present in large numbers, were round, oval, or bacillary in shape, and occurred in a sort of matrix near the nucleus, some of the bodies showed brownian movement Smaller forms were also seen in the cytoplasm of squamous cells, fibroblasts, and even polymorphs It seemed that the larger forms appeared first and that after the development of necrosis the smaller forms were found However, even in the earliest stages some small forms could be found, and it appeared that there must be 2 phases of multiplication of the virus particles In the one type, there is a simple multiplication, in which the small forms divide, in the other type, multiplication occurs, but the particles become entangled in a matrix. The latter type is probably only found in the early stages

(*c*) *Hummelzwen* (1938) employed a most ingenious method of studying the

living chorio-allantoic membrane (duck's egg) *in situ*, using a Heine Ultropak[1] for annular oblique incident illumination. The vaccinial lesions consisted of a mass of infected cells with infiltrating leukocytes, and appeared heaped up and opalescent. At the edge, however, the tissue was not so opalescent, because the cells were not degenerate. Virus bodies could be first seen on the second day after inoculation, when there was a narrow peripheral zone of brilliant particles vibrating in constant brownian movement in a matrix of low viscosity. With the progress of infection, the virus particles increased in numbers, such an increase being always accompanied by a corresponding increase in the volume of the matrix. Sometimes the virus-containing part might become separated from the rest of the cell, the elementary bodies still being retained in the matrix, however. From these studies, Himmelweit concluded that the Guarnieri body is composed of a collection of elementary bodies contained in a matrix.

(*d*) Downie and Dumbell (1947 *b*) studied the inclusions of variola in the chorio-allantois. They could be found even after 24 hours; the inclusions were in the form of irregular eosinophilic granules. Single homogeneous bodies were not found The inclusions of variola were more coarsely granular than those of vaccinia.

Other authors who have demonstrated Guarnieri bodies in the infected chorio-allantoic membrane (of the hen's egg) include Goodpasture and Buddingh (1934), Gross (1937), Mesrobeanu (1937), and Buddingh (1938 *b*).

(*e*) With regard to Guarnieri bodies in *tissue culture*, these have been found to develop in corneal cells prepared by the tube technique, both in epithelium (Rivers, Haagen, and Muckenfuss, 1929 *a*, *b*, *c*), and in fibroblasts (Rhodes and van Rooyen, 1937 *b*); Mitamura *et al.* (1933) and Feller, Enders, and Weller (1940) have also found Guarnieri bodies. Bland and Robinow (1939) showed that when infected corneal epithelial cells were grown in tissue culture, vaccinia virus underwent a progressive and obligatory process of intracellular development. Elementary bodies penetrated the cytoplasm, became enlarged to form inclusions, and altered

homogeneous bodies, then, large homogeneous bodies, then, small networks, later, medium networks, and finally, large networks During the greater part of this process, elementary bodies were absent from the cells, presumably being within the inclusions. At the end of the process, elementary bodies were again found in increased numbers in only those cells containing the largest type of inclusion The inclusions are believed to be an obligatory stage in the multiplication of the virus, and to consist of colonies of elementary bodies enveloped in a matrix, thus supporting von Prowazek's original claim that Guarnieri bodies are *Chlamydozoa*

More recently, Merling has carried out direct microscopic observations on infected cells He produced vaccinial keratitis in the rabbit, detached the corneal cells, and placed them in saline or Tyrode in sealed slides (1940 *a*) Virus was found in the cells 24 hours after inoculation The surface of the cell was first studded with EB's, which later sunk in The cytoplasm appeared dissolved, and the collection of EB's was in brownian movement One cell might contain several of these Guarnieri type inclusions, the average inclusion containing about 150 EB's Disks were also observed in the cytoplasm of the cell, or the inclusion, spheres were found in the inclusions and lying outside the cell EB's were seen to develop into disks, at the periphery of which nodes appeared These formed into separate EB's, and were released into the liquefying center of the disk, giving a small inclusion The inclusions measured 0.5 to 15 μ, the spheres 0.5–1.0 μ, EB's 80–120 mμ, and disks 0.15–0.2 μ.

[1] Ernst Leitz Wetzlar

In other experiments (1940 *b*), observation was carried out for a longer period, and certain additional changes described The commonest long-term change was the appearance of cell extrusions originating from Guarnieri bodies, and displaying a definite increase in the number of virus bodies. Rarer forms were cyst-like extrusions filled to capacity with all forms of virus. He concluded that virus continues to live after the death of the host cell, and confirmed these observations in later work (1943). Virus was also found to grow inside leukocytes, and formed colonies (1945).

(*f*) It is possible that valuable observations may be made by electron microscopy of tissue or exudates (see Fig 29B).

CHAPTER XXX

THE VARIOLA-VACCINIA VIRUS CULTIVATION

INFECTION OF THE EGG WITH VARIOLA

MATERIAL from smallpox lesions produces typical pocks on the chorio-allantois, and this has been made use of in diagnosis (see Ch. XXVII, Lazarus *et al*, 1937,[1] Buddingh, 1938 *b*, 1943, Nelson, 1939, 1940 *b*, 1941. 1943, Irons *et al*., 1941, Bohls and Irons, 1942, North, 1944, North, Broben, and Mengoni, 1944, Downie, 1946, Downie and Dumbell, 1947 *a*, *b*). EB's and inclusions can be found readily. Variola passed on the chorio-allantois does not apparently become converted into vaccinia Buddingh (1938 *b*) found that the pocks were produced by ectodermal hyperplasia, with central necrosis Vesicle formation was observed in the hyperplastic epithelium Small Guarnieri bodies were seen in the less degenerate cells The mesoderm showed edema and infiltration with mononuclears and polynuclears. Entodermal cells were also hyperplastic. Downie and Dumbell recommend examination of the membranes after 48–72 hours. The number of pocks may be considerable, as they are small and dome-shaped. They found inclusions within 24 hours of infection in the form of fine acidophilic granules in the ectoderm Large homogeneous bodies, as found in the cornea, were not found. The chick embryo was not significantly infected. Downie and Dumbell compared the lesions induced by variola and vaccinia, vaccinial lesions were larger, flatter, more necrotic, showed hemorrhage more frequently, and histologically there was more destruction and less proliferation

INFECTION OF THE EGG WITH VACCINIA

Following the pioneer work of Goodpasture, Woodruff, and Buddingh (1932), who showed that vaccinia virus could proliferate when inoculated onto the chorio-allantois of the fertile egg, numerous other workers have studied this reaction[2] (Lehmann, 1934, Pandit and Rao, 1935, Shah, 1935, Sporzynski, 1935, Torres and Teixeria, 1935 *c*, Molina, 1937 *a*, *b*, Stevenson and Butler, 1939, and others, see below). In addition, many workers have grown virus in eggs for use in vaccination (see p 382). The virus infects most regularly by the chorio-allantoic route Hen's eggs are invariably used, the turtle egg is also susceptible (Harris, 1945)

Pathology of Infected Membranes

Naked-eye, the infected membrane usually shows the development of whitish, raised, pock-like lesions known as plaques, which may become confluent

1 *Goodpasture*, W[illegible] membranes in their or[illegible] cine, they found that [illegible] opaque about the site [illegible] this was thick, gray, opaque, and flecked with small hemorrhages Histologically, the membrane was considerably thickened, due to inflammation and hemorrhage At the edge of the lesions there was edema, some hemorrhage, and slight hyperplasia of the ectoderm and endoderm Guarnieri bodies were seen in ectoderm In older areas the ectoderm was necrotic, there was an exudate in the mesoderm of red cells, white cells, and large mononuclears, although the endoderm was hyperplastic, no necrosis was evident They concluded that the virus affected primarily the ectoderm, the mesoderm less, and the endoderm least of all

2. *Tang and Wei* (1937) examined the lesions in infected membranes after 48

1 References are appended at the conclusion of Ch XXXV, p 403 et seq

2 General details of egg technique are discussed in Ch XIII

hours, and found the following changes (the strain of virus used had originated in dermal lymph): Accumulations of cells were seen, due to ectodermal proliferation and cellular infiltration, and in some of these areas necrosis had given rise to umbilication Where there was no necrosis, there was a translucent superficial opacity which faded into the normal tissue at the edges of the lesion Cells at the periphery of the lesion were very irregular in size, and contained numbers of granular structures

3. *Levaditi and Voet* (1937) studied the reaction to both dermo- and neuroviruses The first change noted was an ectodermal thickening, from the 18th hour onward The epithelial cells showed numerous mitotic figures, the cytoplasm was swollen, vacuolated, and contained inclusions A mesodermal reaction was noticed from 25 hours onward, being evidenced by infiltration with leukocytes and histiocytes, there was a hyperplasia of the vascular endothelium and a new formation of vessels. At this time, vesicle formation was noted in the epithelial cells, and there were more Guarnieri bodies Between the third and fourth day ectodermal proliferation was very marked, and cell nests were formed in the mesoderm. Later, pustules were produced

4. *Stevenson and Butler* (1939) reported that to naked-eye observation there was no difference detected in the course of over 100 egg passages of dermal virus After 4 days' growth the most characteristic lesion was a confluent plaque, without hemorrhage.

5. *Buddingh* (1936 *a*) has compared the pathological features of membranes infected with neurotesticular and dermal strains of virus The dermal strain showed a special tendency to involve ectoderm, while the neurotesticular was characterized by hemorrhage and a predilection for mesoderm.

6 *Keogh* (1936) studied the difference in the reactions produced by dermal and neurotropic viruses The pocks produced by the neurovirus strain were smaller and more defined than those produced by dermal virus, but there was more necrosis with the former.

7 *Mesrobeanu* (1937) also studied the histological changes in infected egg membranes, according to whether dermo- or neuro-vaccinia was used. With dermovaccine, the changes were more pronounced in the first 48 hours and were more widespread The lesions produced by neurovaccine were more focal, there were fewer leukocytes in the mesoderm, in fact there was a special tendency to histiocytic increase

Normal Corpuscles

In their work on the infectivity rate of EB's prepared from chorio-allantoic suspensions, Levaditi *et al* found that certain "normal corpuscles" were present that closely resembled vaccinial EB's (Levaditi, 1939 *c*; Lépine, Levaditi, and Giuntini, 1942 *a*, *b*, Pérault, 1942) These normal corpuscles were particularly evident in suspensions prepared from membranes shortly after infection, after 2–4 days' incubation the vaccinial EB's were more numerous than the normal corpuscles

The Effect of Passage on the Properties of Egg Virus

There is some difference of opinion as to whether egg passage alters the properties of virus. Lehmann (1934), for example, found that passage increased the virulence of virus for the rabbit. Tang and Wei (1937) found that virulence increased *pari passu* with the number of transfers on the chorio-allantois After a number of passages, rabbits injected with suspensions of infected membrane often died Further, the chick embryos were frequently killed in the later passages, although this had not occurred at the beginning of the work, from the 15th generation onward, pustules occurred on the toes or beak of the embryo

On the other hand, Stevenson and Butler (1935) detected no differences between 12-passage virus and calf lymph on skin inoculation of monkeys and calves

Continuing their work, they reported (1939) that somewhere between the 24th and 55th subcultures, and in later passages, a 1/100 dilution of chick membrane lymph gave a somewhat similar infective response to that produced by a 1/1,000 dilution of calf lymph. Echenique-Guzman (1937) found that repeated egg passage did not augment the infectivity of a dermovirus or of a neurovirus strain. Kunert (1935) actually found that the effect of passage on the Berlin strain of virus was to induce a decrease in its virulence. Rabbit passage, however, restored its original activity.

Buddingh (1936 *a*) studied the effect of passage on the properties of a neurotesticular strain of virus which produced a hemorrhagic lesion on the chorio-allantois and the rabbit's skin, and found that the hemorrhagic nature of the lesions was maintained through 50 egg transfers.

Stevenson and Butler (1939) have carried out considerably over 100 egg passages with a dermal strain of virus. With regard to the lethal effect on the embryo, they found that this was slight in the first 2 passages or so, from the 3rd to the 14th (in some cases the 29th) embryos, however, died more frequently; finally, from the 50th to the 126th the virus was not lethal to the embryo.

Further, they reported that the reactions produced by inoculation of the skin of rabbits, monkeys, and calves with egg virus resembled in every important respect those produced by calf lymph. The lesions were, however, slightly slower in development, the surrounding skin was less congested, and the crusts were slighter. They failed to find that growth in the egg endued the virus with any tendency to generalize on inoculation, nor did any neurotropic tendencies present themselves on direct intracerebral injection.

Buddingh (1943) examined a strain after 240 passes. The lesions produced in the rabbit skin were milder than those produced by calf lymph

The Chick Embryo in Vaccinial Infection of the Egg

Buddingh (1936 *b*) has published a detailed study of the reaction of the chick embryo to infection of the chorio-allantois with dermal virus. In short, he found areas of focal necrosis in the liver and spleen, with pocks on the skin and mucous membranes. Virus was widely distributed—occurring in the liver, spleen, skin, intestines, kidney, heart, marrow, but only to a slight extent in the brain. Stevenson and Butler (1939) did not, however, obtain nearly such severe reactions in chick embryos.

The embryo may fail to grow at the normal rate (Hoffstadt and Tripi, 1946 *b*).

Applications of the Egg Technique

1 *For human vaccination* This is probably the most important application of the egg technique. Infected membranes may be ground up and used as a source of vaccine for human inoculation This question is discussed more fully in the section on vaccination (see p 382).

2. *Titration of virus and antiviral sera* Keogh (1936) has shown that inoculation of the chorio-allantois can be used as a means of estimating the potency of vaccinial suspensions. He has found that if suspensions of virus are inoculated into eggs in suitable dilutions, then discrete lesions are produced, and that the titer obtained by counting these pocks corresponds to that yielded by intradermal inoculation of animals. He has also shown that immune sera may be titrated by mixing with virus and inoculating eggs Account is then taken of the percentage reduction effected in the number of pocks developing on the chorio-allantois. Burnet and Faris (1942) also studied the titration of virus, but Haagen and Crodel (1939–40) did not agree that the chorio-allantois could be used as an accurate method of titration.

3. *Other applications.* Keogh (1937) studied the kinetics of the disinfecting action of formalin on vaccinia virus by the chorio-allantoic technique. Without

entering into details, it appeared that the formula $Kct = \log \frac{V}{v}$ applied to this reaction (V = original number of virus particles, v = number of particles surviving the disinfection); further the reaction was approximately doubled by raising the temperature from 23° to 37° C. The membranes can be used as a test of inactivation of virus by chemicals (Dunham and MacNeal, 1942; Cutting *et al*, 1947).

The infected chorio-allantoic membrane has been used as an antigen in the complement fixation test (Kunert and Wenckebach, 1936).

Other Routes of Inoculation

It has been reported that the egg is susceptible to yolk sac inoculation, and less readily susceptible to infection in the allantoic sac (Groupé and Rake, 1947).

IN VITRO CULTIVATION OF VACCINIA

1. Media Containing Fungi or Yeasts

It has been claimed that growth of vaccinia can be obtained in media containing fungi (Isabolinski *et al.*, 1935), or yeast (Silber and Wostrouchowa, 1933 *a*, *b*, Khurgina, 1935, Silber, 1935) Amies (1934 *b*), Voet (1935), and Lenz (1937) were unable to obtain growths.

2. Growth in Cell-free Media

Claims have been made that vaccinia [illegible] free of whole or viable cells, known a [illegible] 1930, 1931; McClean and Eagles, 1931, E [illegible] also Ch XII). Although virus may survive in the presence of [illegible] substances elaborated by cells (Muckenfuss and Rivers, 1930, Muckenfuss, 1931), Eagles's experiments have not been generally confirmed (see Krontowski *et al*, 1933, Rivers and Ward, 1933 *a*, *b*)

3. Growth in the Presence of Living Cells (Tissue Cultivation) [1]

Certain preliminary observations showed that some survival, and even definite proliferation, of vaccinia virus occurred in association with animal tissue suspended in serum or other nutrient fluid (Steinhardt *et al*, 1913, Steinhardt and Lambert, 1914, Harde, 1916; Fornet, 1922; Parker, 1923–4, Parker and Nye, 1925, Craciun and Oppenheimer, 1926, Carrel and Rivers, 1927, Levaditi, 1927, Haagen, 1928).

[illegible]

land, Laing, and Lyth, 1932) In later work, Maitland and Laing (1941) showed [illegible]

[illegible]

cinia using minced chick embryo as a source of living cells (see also Rivers and Ward, 1931).

At the present day, the tissues most commonly used to obtain growths of vaccinia are rabbit testis or kidney, or minced chick embryo, spleen and cornea may also be employed, but are not so effective, cultures of Kupffer cells (Beard and Rous, 1938), and rabbit mononuclear cells have also been used (Florman and Enders, 1942).

The results of the pioneer workers have been abundantly confirmed, and many authors have succeeded in cultivating vaccinia virus in the types of tissue culture

[1] For fuller details of tissue cultivation technique see Ch XII

introduced by Maitland and by Rivers (Eagles and McClean, 1929, 1930, Hauduroy, 1929, Nye and Parker, 1929, Rivers, Haagen, and Muckenfuss, 1929 *a*, Kimura and Fujisawa, 1929–30; McClean and Eagles, 1931, Breinl, 1933; Haagen, 1933, Rivers, Sprunt, and Berry, 1933, Herzberg, 1935, Rao *et al.*, 1935–6, Haagen, 1936 *b*, Haagen and Crodel, 1936–7, Galli, 1937, Plotz, 1937, 1938 *a*, *b*, Plotz and Lépine, 1938, Enders and Florman, 1942, Thompson and Coates, 1942 and others mentioned below.

Kurotchkin (1939) has claimed that growth occurs in chick embryo tissue on the surface of agar slopes Thompson and Coates (1939) have grown virus in columns of Maitland's medium up to 115 mm deep Yaoi and Arakawa (1939 *a*) grew vaccinia in deep columns of Tyrode and minced chick embryo, with oxygenation The virus grows well in roller tube cultures, rapidly increases to maximum titer, and remains at or near maximum for at least 9 weeks, living cells are essential, and it seems that virus is being continually produced, not merely preserved (Feller, Enders, and Weller, 1940).

The Effect of Passage on Culture Virus

Certain strains of virus may be readily adapted to growth in tissue culture, and numerous transfers made. In other cases, however, continued propagation may prove rather difficult. When culture virus shows evidence of becoming reduced in potency, one or more passages through rabbits serve to restore its original characteristics (Ch'en, 1933–4, Coffey, 1934). Although culture virus does not usually alter in any important respect with regard to the nature of the lesions produced on injection of animals, Haagen *et al* (1932) reported that a strain altered to produce hemorrhagic and necrotic lesions in the rabbit's skin. Parker, Bronson, and Green (1941) worked with a strain that had lost most of its virulence for rabbits on prolonged cultivation, it did not prove possible to restore this virulence by various procedures.

Preservation of Culture Virus

Various methods have been adopted to store tissue culture virus in a suitable virulent condition For example, it can be stored at +5° C. for at least 64 days, if mixed with glycerol and sealed (Li and Rivers, 1930) Later it was reported that virus could be stored for at least a year in 50 per cent glycerol at −10° C, and at +3° C. (Rivers and Ward, 1933 *c*) Mixed with 2½ per cent. gum acacia, frozen, desiccated, and sealed *in vacuo*, virus remains active for a month at 37° C (Rivers and Ward, 1935)

If the culture fluid is diluted with equal parts of horse serum and desiccated *in vacuo* from the frozen state, virulence can be maintained at 4° C for at least 69 days (Lloyd and Mahaffy, 1935–6) Togounova *et al* (1935) have claimed that on ice, or desiccated, culture virus survives for over one year

Applications of the Tissue Culture Technique

1 Tissue culture may be used as a source of vaccine for human inoculation (see Ch. XII)

2 Tissue culture has been employed as a method of studying the theoretical aspects of the vaccinial antigen-antibody reaction (Stoel, 1930–1, Sabin, 1935 *b*, Magrassi and Hallauer, 1936)

3. Culture virus may be used as an antigen for immunizing animals. For example, Maitland and Laing (1930) found that the serum of rabbits immunized against culture virus fixed complement with calf lymph Togounova (1935) found that the sera of animals immunized with culture virus developed virucidal, agglutinating, and complement fixing antibodies (see also Plotz, 1938 *d*)

4. Culture virus may be used as an antigen in serological tests For instance, Maitland and Laing (1930) found that antivaccinial serum fixed complement in the presence of culture virus (see also, Gilmore, 1931, Barg and Rudenko, 1934)

CHAPTER XXXI

VARIOLA-VACCINIA VIRUS· HEMAGGLUTINATION

It has been found that variola and vaccinia virus may agglutinate chick red cells. A similar type of agglutination, which differs somewhat from that produced by influenza (Ch LXI), is given by the virus of mouse ectromelia (Nagler, 1942,[1] North, 1944, Burnet, 1945, 1946, Shubladze and Soloviev, 1945, and others to be mentioned). The hemagglutination reaction with chick cells may be referred to as the CCA reaction, and the vaccinia and ectromelia hemagglutinins as V and E HA

SOURCE OF V AND E HA

Hemagglutinin is most readily demonstrated in suspensions of infected chorio-allantoic membranes

Suspensions of organs of chick embryos inoculated intravenously with ectro-

1. VHA was found in the early stages of dermal infection in rabbits, and the ratio between hemagglutinin (HA) and virus (V) titers could be expressed in the form HA/V 10^{5}. The ratios in the superficial scrapings from several rabbits 3 days after inoculation varied from 0 08 to 1 6, whereas in the skin suspensions they were much higher, 4 4 to 23 That is to say, the ratio of VHA to virus was higher in the deeper layers than in the superficial scrapings

2. Virus was found in almost undiminished amount in the scab formed after 7–8 days, and in the underlying skin, but at this time there was a rapid disappearance of hemagglutinin from both sites From 7 days onward, antihemagglutinins were found in the skin

3 Crude calf lymph was emulsified in saline to form a 20 per cent. suspension, and was then centrifuged The supernatant fluid had no hemagglutinating activity. It was then titrated for antihemagglutinin against 5 hemagglutinating doses of VHA, and a titer of 25–35 was obtained. The same fluid was tested against ectromelia and influenza A hemagglutinins with the following results, vaccinia 28, ectromelia 8.5, influenza less than 4 This behavior, and the results of further tests, suggested that the inhibitory agent in calf lymph was an antibody resembling serum antibody.

4 In chorio-allantoic lesions due to vaccinia or ectromelia there was also a difference in the relative virus hemagglutinin content of the superficial (necrotic) and deeper tissues The HA/V 10^{-5} ratios for the deeper portion of the membrane lesions were 10–20 times as high as those for the superficial scrapings If saline suspensions from superficial chorio-allantoic lesions were allowed to stand in the refrigerator for 10 or more days, their hemagglutinating activity showed a marked increase This effect was probably due to the liberation of lipoid material, and was inhibited by dilute normal serum These examples stress the importance of controlling the specificity of hemagglutination reactions with separate tests employing immune and normal serum

The points of interest brought out in this work were the low hemagglutinin titer of the superficial layers of rabbit skin and chorio-allantois as compared with their high virus content The hemagglutinin is presumably produced predominantly

[1] References are appended at the conclusion of Ch XXXV, p. 403 et seq

introduced by Maitland and by Rivers (Eagles and McClean, 1929, 1930, Hauduroy, 1929, Nye and Parker, 1929, Rivers, Haagen, and Muckenfuss, 1929 *a*; Kimura and Fujisawa, 1929–30; McClean and Eagles, 1931; Breinl, 1933; Haagen, 1933, Rivers, Sprunt, and Berry, 1933, Herzberg, 1935; Rao *et al*, 1935–6; Haagen, 1936 *b*, Haagen and Crodel, 1936–7, Galli, 1937, Plotz, 1937, 1938 *a*, *b*; Plotz and Lépine, 1938, Enders and Florman, 1942; Thompson and Coates, 1942 and others mentioned below.

Kurotchkin (1939) has claimed that growth occurs in chick embryo tissue on the surface of agar slopes. Thompson and Coates (1939) have grown virus in columns of Maitland's medium up to 115 mm deep. Yaoi and Arakawa (1939 *a*) grew vaccinia in deep columns of Tyrode and minced chick embryo, with oxygenation. The virus grows well in roller tube cultures, rapidly increases to maximum titer, and remains at or near maximum for at least 9 weeks, living cells are essential, and it seems that virus is being continually produced, not merely preserved (Feller, Enders, and Weller, 1940).

The Effect of Passage on Culture Virus

Certain strains of virus may be readily adapted to growth in tissue culture, and numerous transfers made In other cases, however, continued propagation may prove rather difficult. When culture virus shows evidence of becoming reduced in potency, one or more passages through rabbits serve to restore its original characteristics (Ch'en, 1933–4, Coffey, 1934). Although culture virus does not usually alter in any important respect with regard to the nature of the lesions produced on injection of animals, Haagen *et al* (1932) reported that a strain altered to produce hemorrhagic and necrotic lesions in the rabbit's skin. Parker, Bronson, and Green (1941) worked with a strain that had lost most of its virulence for rabbits on prolonged cultivation, it did not prove possible to restore this virulence by various procedures.

Preservation of Culture Virus

Various methods have been adopted to store tissue culture virus in a suitable virulent condition For example, it can be stored at +5° C. for at least 64 days, if mixed with glycerol and sealed (Li and Rivers, 1930) Later it was reported that virus could be stored for at least a year in 50 per cent glycerol at −10° C, and at +3° C (Rivers and Ward, 1933 *c*) Mixed with 2½ per cent. gum acacia, frozen, desiccated, and sealed *in vacuo*, virus remains active for a month at 37° C (Rivers and Ward, 1935)

If the culture fluid is diluted with equal parts of horse serum and desiccated *in vacuo* from the frozen state, virulence can be maintained at 4° C for at least 69 days (Lloyd and Mahaffy, 1935–6) Togounova *et al.* (1935) have claimed that on ice, or desiccated, culture virus survives for over one year.

Applications of the Tissue Culture Technique

1 Tissue culture may be used as a source of vaccine for human inoculation (see Ch XII)

2. Tissue culture has been employed as a method of studying the theoretical aspects of the vaccinial antigen-antibody reaction (Stoel, 1930–1, Sabin, 1935 *b*, Magrassi and Hallauer, 1936)

3 Culture virus may be used as an antigen for immunizing animals For example, Maitland and Laing (1930) found that the serum of rabbits immunized against culture virus fixed complement with calf lymph Togounova (1935) found that the sera of animals immunized with culture virus developed virucidal, agglutinating, and complement fixing antibodies (see also Plotz, 1938 *d*).

4 Culture virus may be used as an antigen in serological tests For instance, Maitland and Laing (1930) found that antivaccinial serum fixed complement in the presence of culture virus (see also, Gilmore, 1931, Barg and Rudenko, 1934)

AGGLUTINATION BY LIPOIDS

Burnet and Stone (1946) showed that various tissue lipoids, e g, from the normal chorio-allantois, give hemagglutination resembling that produced by VHA. This type of hemagglutination, however, is readily inhibited by dilute normal serum, whereas virus hemagglutination is not Stone has carried out more extensive experiments

1. VHA and EHA are inactivated by phospholipoid-splitting enzymes, such as *Cl welchu* α toxin, and cobra venom (Stone, 1946 *a*). When VHA was incubated at 37° C with toxin it was progressively reduced in titer. No decrease in titer followed treatment with heated toxin for 4 hours, although there was slight inactivation after 24 hours The inactivation of VHA by toxin was inhibited by the inclusion of antiserum to *Cl. welchii* α toxin type A. There was no apparent destruction of VHA in the absence of calcium ions. As calcium or magnesium ions are required for the action of the α toxin (lecithinase) of *Cl welchu*, it is suggested that lecithinase is responsible for the inactivating effect of toxin. A preparation of hyaluronidase, also produced by certain strains of *Cl. welchu*, did not inactivate VHA.

EHA was similarly susceptible to inactivation by *Cl welchii* type A toxin, the capacity to agglutinate mouse cells appeared to be destroyed in parallel with hemagglutinating capacity for fowl cells.

Cobra venom, which contains a different type of lecithinase rapidly destroyed both VHA and EHA

It seems highly probable that lecithinase is responsible for the inactivation of VHA and EHA by *Cl welchu* toxin It is concluded that VHA and EHA contain a phospholipoid, most probably lecithin, and that enzymic breakdown of this part of the complex destroys its hemagglutinating properties.

2 Attempts to isolate the active hemagglutinating principle from extracts of chick embryo liver, and baker's yeast, yielded little information (Stone, 1946 *b*) From a limited survey of the hemagglutinating properties of various lipoids, it did not appear that [illegible]
in tissue extract
cluding beef hea
that a mixture c
and the lecithin could be replaced by sphingomyelin, and the cholesterol by (*a*) ergosterol, maize sterols, or (*b*) cardiolipin without loss of activity. Taking a lecithin-cholesterol mixture as a typical example, the general properties were found to agree with those of the tissue lipoid hemagglutinin. In the bulk of the tests, the increased activity in mixed preparations of lipoids was demonstrable only with susceptible fowl cells. The weak hemagglutination of insusceptible cells which is shown by some compounds such as cholesterol and cardiolipin is actually depressed by the addition of lecithin

Stone concludes that the fact that alcoholic mixtures of purified lipoids (such as lecithin and cholesterol) are active hemagglutinating agents when diluted in saline, offers a reasonable explanation of the activity of tissue extracts In any such extract there will normally be a mixture of phospholipoids and sterols, and the main hemagglutinating activity can be accounted for by lecithin-cholesterol in animal extracts, and lecithin-ergosterol in yeast extracts It may be, as suggested by Eagle in connection with the Wassermann antigen, that the phospholipoid is distributed on the surface of cholesterol aggregates and stabilizes the cholesterol suspension in the aqueous medium Whether the two components of the mixtures have specific configurative parts to play in the hemagglutination reaction, or whether one merely serves as an inactive nucleus for the suitable distribution of the other cannot yet be determined

The depressant effect of lecithin on the agglutination of insusceptible cells by

in the epithelial cells, and it is suggested that it may be oxidized and destroyed in the superficial layers.

The failure of calf lymph of high virus content to show any specific hemagglutinin may be due partly to oxidation in the superficial layers, but there is in addition an actively inhibitory substance present, which is almost certainly antibody. This antibody is possibly produced in the immediate vicinity of the lesion.

The fact that nonspecific hemagglutinins, probably lipoid in character, develop in chorio-allantoic scrapings when left in the refrigerator, indicates an important potential source of error in experimental work.

CELLS AGGLUTINATED

Clark and Nagler (1943) found that about 50 per cent. of fowls give red cells agglutinable by vaccinia, and agglutinability develops in 2–4 weeks after hatching Variola agglutinates fowl cells less readily than does vaccinia

Fowls could be classified into 3 groups according to whether cells were agglutinated by both viruses, strongly, weakly, or hardly at all (Burnet and Boake, 1946).

Ectromelia agglutinates mouse cells, but vaccinia does not (Burnet and Boake, 1946). Pigeon cells have also been used (Burnet and Stone, 1946). Clark and Nagler (1943) tested a wide range of cells (see Ch. LXI).

CCA-INHIBITION

CCA is inhibited by antisera prepared experimentally in animals or obtained from convalescents. These antibodies develop after primary "takes" on vaccination or revaccination, and less markedly after accelerated or "immune" reactions on revaccination (Nagler, 1942, 1944).

Antiserum inhibits the agglutination caused by either variola or vaccinia (North, 1944) Inhibition can also be shown with ectromelia antisera (Burnet and Stone, 1946).

SOME CHARACTERS OF HEMAGGLUTINATION

No significant differences have been noted in the character of the hemagglutination produced by vaccinia and ectromelia viruses, but both ectromelia and vaccinia hemagglutinins differ considerably from the influenza-Newcastle type of agglutinins

1 Agglutination with vaccinia and ectromelia occurs best at 37° C, but that with influenza is best at lower temperatures. The apparent titer rises if cells and virus are allowed some time for interaction before being finally shaken and allowed to settle, especially when lower concentrations (1 per cent) of susceptible fowl cells are used (Burnet and Boake, 1946)

2 No evidence of elution of the hemagglutinins after prolonged contact has been obtained, susceptible fowl cells rendered inagglutinable to most influenza viruses are s [illegible] ia hemagglutinin (Burnet and Boake, [illegible] if VHA is removed by exposure to [illegible]

3. The hemagglutinins of vaccinia and ectromelia viruses are soluble and distinct from the virus particles, as can be shown by suitable absorption experiments The hemagglutinin of influenza virus is a function of the elementary bodies That VHA and EHA are distinct from the virus particles has been demonstrated by Burnet and Stone (1946) The hemagglutinin is readily removed from stock virus suspensions by absorption with susceptible fowl red cells, to a very limited extent with insusceptible cells and not at all by embryonic cells The virus content is essentially unaltered by these procedures. Centrifugation of infective suspensions at 15,000 r p m results in practically all the virus being removed from the supernatant fluid, which fluid however shows no significant loss in hemagglutinins

CHAPTER XXXII

THE VARIOLA-VACCINIA VIRUS: EFFECT OF PHYSICAL AND CHEMICAL AGENTS[1]

THE EFFECT OF PHYSICAL AGENTS ON VACCINIA VIRUS

Heat The virus is fairly readily destroyed by heat, for example, when heated in Locke's solution to 55° C. for 20 minutes, or to 37 5° C for 24 hours (Nye and Parker, 1929)[2] It has, however, been claimed that although neurovirus is destroyed at 55° C for 1 hour, dermovirus is not (Levaditi and Nicolau, 1923 *a*) With regard to the time of survival at 37° C, it has been stated that suspended in a special buffer solution, virus retains its infectivity for as long as 66 days (Silber and Wostrouchowa, 1932). The effect of heat on antigenic properties is discussed on p. 359

Cold. As in the case of other viruses, infected suspensions can be stored in the cold for prolonged periods Buddingh (1938 *b*), for example, found virus (suspended in saline) to retain its activity at 0° C for at least 5 weeks For conservation of infected egg membrane, Haagen (1939) has recommended that it be sealed hermetically and kept at 4° C.

Desiccation Vaccine virus can be maintained in an active condition for prolonged periods if infected tissue, such as testis, is rapidly desiccated *in vacuo* (preferably from the frozen state), and stored in sealed test tubes, it may survive for 3 years (Hoffstadt and Tripi, 1946 *a*) Dearing (1934) also carried out experiments on dried virus

Supersonic waves Although crude suspensions were not found to be inactivated by supersonic waves, chemically "purified" suspensions were destroyed by very short exposures (Yaoi and Nakahara, 1934).

Ultrapressure. Vaccinia has been found to resist 1,800 atmospheres for 45 minutes, but to be destroyed by 4,500 atmospheres applied for the same time (Basset *et al*, 1933).

pH Moriyama (1937 *a*) found that activity was slowly lost when hydrochloric acid was added to vaccinia virus to produce a pH of between 3 and 5. The addition of caustic soda at once restored activity, but this reaction eventually became irreversible

The electrical charge of vaccinia virus A number of authors has studied the

(Rivers and Gates, 1928, Kirstein, 1929, Linden and Schwarz, 1931, Barkad *et al*, 1932), and to x-rays (Lacassagne and Nyka, 1938) Polonium destroys the virus (Bonet-Maury and Olivier, 1938) *In vivo* it has been shown that ultraviolet radiations may prevent the development of an eruption due to the inoculation of virus (Carnot *et al*, 1926) Rivers *et al* (1928) found that rabbit's skin treated for a few minutes with ultraviolet light was less susceptible to vaccination than was untreated skin Herzberg (1933 *b*) found that ultraviolet irradiation applied up to the 8th hour after inoculation prevented the appearance of pustules Alpha rays of radon destroy infectivity (Levaditi and Pérault, 1943)

Le Fèvre de Arric (1927) reported that the exposure of the rabbit's skin to x-rays rendered it insusceptible to vaccination

[1] See also the effect of physical and chemical agents on EB's (p 338) The reported effects of these agents on EB's, and less purified forms of virus, are not necessarily identical

[2] References are appended at the conclusion of Ch XXXV, p 403 et seq

cholesterol and cardiolipin would explain the complete inactivity of tissue extracts against insusceptible cells, even though they contain active compounds such as cholesterol and cardiolipin

The properties of hemagglutination and activity in WR both appear to be based on suitably dispersed lipoid combinations, but the Wassermann activity is much more restricted than the agglutinating effect, which is shown by mixtures serologically inert.

Lipoid hemagglutination is of biological interest, chiefly in its bearing on the problem of the nature of the specific hemagglutinins of vaccinia and ectromelia viruses. The provisional picture is of the vaccinia hemagglutinin as a relatively well-defined and stable complex of a virus antigen and a phospholipoid, the latter being responsible for union with the surface of the cell

THE PROTECTIVE EFFECT OF CERTAIN AGENTS ON THE ACTIVITY OF VACCINIA VIRUS

The activity of vaccinia virus can be maintained for considerable periods when suspended in the presence of certain substances e.g, broth, glycol, and glycerol, gum acacia (see Goodpasture and Buddingh, 1936); milk, lecithin, or egg yolk (Hirano, 1937), normal inactivated rabbit serum (Goodpasture and Buddingh, 1936); saccharose (Akasawa, 1936), cysteine hydrochloride (Long and Olitsky, 1929–30). Extensive experiments in this connection have been carried out by Buddingh (1938 *a*), using the following substances 30 per cent. gum acacia in saline; 3 per cent granular gastric mucin, equal parts sterile egg yolk and 50 per cent. glycerol, sterile 0 85 per cent. saline, normal inactivated sterile rabbit serum, normal inactivated sterile beef serum, and 50 per cent. glycerol in saline He found that egg-cultured virus retained some infectivity at 37° C. for at least 7 weeks when suspended in sterile rabbit or ox serum.

PHYSICAL AND CHEMICAL "PURIFICATION" OF VACCINIA VIRUS

Numerous attempts have been made to reduce the quantity of the noninfective material in vaccinial suspensions by elution, adsorption, precipitation, and other procedures (Awad, 1931, Sato and Kodama, 1931; Tang, 1932, Kodama, 1933 *a*, *b*, Yaoi and Kasi, 1929 *b*, 1931 *a*, 1933, Yaoi, 1931, 1934, 1935 *a*, *b*, 1936 *c*). The methods used have included the following adsorption with charcoal, glass, kieselguhr, and kaolin (Gins, 1914, Awad, 1931; Tang, 1932), adsorption and precipitation by hydroxides or phosphates of aluminium, iron, or zinc have also been used (Kodama, 1933 *a*, *b*). Kligler (1934–5) reported that by adsorption with kaolin, and successive elutions with ammonia, it was possible to obtain a potent suspension of virus, this

phenol and sodium chloride are finally added

The method of iso-electric precipitation of virus-containing suspensions was employed by Behrens and Nielsen (1935), who obtained water-clear virus suspensions with a high infective titer, from which up to 85 per cent. of protein was removed (see also Behrens and Morgan, 1932).

CHEMOTHERAPY OF VACCINIAL INFECTIONS

In general, vaccinia virus is little affected by any chemotherapeutic agent. For example, Andrewes, King, and van den Ende (1943) tested 74 compounds *in vitro*, but none was of any value

Sulfonamides have no effect on vaccinial infections (Bruni and Buda, 1939, Kolmer and Brown, 1941, Osberghaus, 1942, Thompson, 1947).

Thompson (1947), however, who studied a number of metabolites, metabolite-antagonists, and enzyme-inhibitors in infected cultures, found the following to be inhibitory dinitrophenol, malonic acid, cyanide, atabrine, proflavine, iodoacetic acid, and ascorbic acid

Antibiotics. Most workers have found that *penicillin* has no virucidal effect on the virus *in vitro* or *in vivo* in man, animals, cultures, or eggs (Andrewes, King, and van den Ende, 1943, Parker and Diefendorf, 1944, Diaz Romero, 1945, Kolmer

Filtration. Many workers have been unable to secure infective filtrates of vaccinia-infected tissue suspensions. Careful attention to a number of technical details is necessary, however, and if these are attended to, filtrability can be demonstrated (see also Ch. IV). Ward (1929), for instance, recommended (*a*) the use of fresh vaccine pulp; (*b*) the grinding of this pulp with pulverized glass (Pyrex brand) in a glass mortar, (*c*) the emulsification of pulp in hormone broth, (*d*) centrifugation, and the passage of the supernatant only through the filter. The following filters have all been shown to "pass" the infective agent of variola-vaccinia (the filtrate is, however, always considerably less infective than the unfiltered material): Berkefeld V, N, and W, Chamberland L_3; collodion membranes; Kitasato, Mandler (Negri, 1905, 1906; Carini, 1906; Nicolle and Adil-Bey, 1906, Casagrandi, 1908; Ward, 1929; Ward and Tang, 1929; Yaoi and Kasai, 1929 *c*, *d*; Monteiro and Godinho, 1930; Green and Eagles, 1931, Hirano, 1931 *a*, and others, see Thomson, 1924).

Centrifugation. Vaccinia virus is partly deposited by comparatively low-speed centrifugation, e g, at 6,000 r p.m. for 2 hours (Bland, 1929; see also Tang, 1930) Using an angle instrument, EB's can be deposited more quickly and at a lower speed.

PHOTODYNAMIC INACTIVATION OF VACCINIA VIRUS

A number of dyes have been found to destroy vaccinia virus *in vitro* in the presence of light. Friedberger and Yamamoto (1909 *a*, *b*), for example, found that neutral red (1/10 million) destroyed virus in sunlight in 7 hours. Eosin and rose bengal solutions have a similar photodynamic effect (Barkad *et al.*, 1932).

Herzberg (1931 *a*, *b*) has also studied this question and obtained the following results. methylene blue diluted 1/1 million destroyed virus in sunlight in less than 30 seconds, and in diffused daylight within 2 minutes. After exposure to the action of diffused daylight for 1 hour, virus was completely destroyed by methylene blue *1/20 million, sanoflavine and trypaflavine 1/50 million. In the dark, these dyes* diluted 1/1,000 to 1/1 million were quite ineffective. Herzberg (1933 *b*) later studied the photodynamic effect of
Perdrau and Todd (1933) also
by methylene blue (1/100,000)
(1936) who report that vaccinia virus is destroyed by the photodynamic effect of methylene blue, toluidine blue, methylene green, thionin, and crystal violet in certain dilutions

In vivo the activity of certain thiacines has also been demonstrated Thus, rabbits were inoculated dermally with lymph and 1 to 2 hours later thiacine solution injected intravenously, the animals then being exposed to sunlight for an hour. No pustules formed in these animals (Herzberg, 1931 *a*, *b*).

Herzberg (1933 *b*) found that no lesions developed after scarification if methylene blue was given intravenously up to 24 hours later, and ultraviolet or sunlight irradiation carried out

Perdrau and Todd (1933) applied virus to the scarified skin of the rabbit, methylene blue was administered intravenously, and irradiation applied. There was no reaction if the dye was given up to 18 hours after the virus. Experiments were also carried out on the cornea, which was scarified with virus, the conjunctival sac then being washed out with dye. This treatment prevented the onset of keratitis if given up to 4 hours after the virus

Perdrau and Todd (1936) studied the time taken for virus to penetrate the cells of the host, after inoculation into the rabbit's testis At varying times after injection the testes were removed, suspensions prepared and exposed to the photodynamic effect of methylene blue They found that virus was not protected from the photodynamic effect until after 10½ hours of *in vivo* contact. Presumably, therefore, this time was required for the virus to penetrate the host's cells.

CHAPTER XXXIII

THE VARIOLA-VACCINIA VIRUS: IMMUNITY

A. EXPERIMENTAL AND THEORETICAL ASPECTS

1. The Antigenic Structure of Vaccinia Virus

OF RECENT YEARS very great advances have been made in our knowledge of the antigenic structure of vaccinia virus Much of this advance dates from Gordon's demonstration that flocculation occurs when a suspension of variola scabs is mixed with antivaccinial serum Next, it was found by the work of Tulloch and Craigie that vaccinia virus treated by Seitz filtration can be separated into 2 moieties, the one contains the elementary bodies and is not markedly flocculable by antiserum, while the other moiety is noninfective but markedly flocculable Later, it was found that elementary bodies contain antigenic components, known as L (labile) and S (stable). LS antigen is found in considerable amount in suspensions of dermal pulp. Independent L and S antibodies develop when LS antigen is inoculated into animals When antivaccinial serum is mixed with elementary bodies, then agglutination occurs, but if the serum is mixed with a suspension, then flocculation occurs, the same LS antigen and antibody being concerned in both reactions.

This subject of the antigenic structure of vaccinia virus has been studied by numerous authors (Burgess, Craigie, and Tulloch, 1929,[1] Craigie and Tulloch, 1931; Tulloch, 1931–2, Craigie, 1932 *a*, *b*, 1933, 1934, Smith, 1932, Craigie and Wishart, 1934 *a*, *b*, 1935, 1936 *a*, *b*, *c*, Salaman, 1934, 1937, 1938, Ch'en, 1934–5, Parker and Rivers, 1935, 1937, Wishart and Craigie, 1936, Smadel and Wall, 1937, Amies, 1938, Parker, 1938 *a*).

The effect of Seitz filtration on virus suspensions.

Suspensions of vaccinia virus can be separated into 2 moieties by the following method (Tulloch, 1931–2): The material is filtered through a Seitz EK disk, thus yielding a filtrate which is flocculable but noninfective, sometimes it is necessary to use double disk filtration to obtain a filtrate which is noninfective. Next, the disk is washed to remove any of the flocculable material, then it is reversed, and washing is carried out in the opposite direction. This operation yields a material which is infective, but not markedly flocculable, and contains the elementary bodies.

The LS antigen: work of Craigie and Wishart.

Craigie and Wishart have shown that various suspensions of vaccinia virus contain an antigen known as LS which is composed of 2 components L and S The LS *antigen is known as the specific flocculable* (precipitable) substance or the specific filtrable substance

The L antigenic component The antigenic properties are destroyed at 70° C., but resist the action of ether, L antigenic component is precipitated by CO_2 (Craigie and Wishart, 1936 *c*, Wishart and Craigie, 1936)

The S antigenic component. This component withstands 70° C.; its antigenic power is considerably lowered by steaming (Craigie and Wishart, 1936 *c*), but is unaffected at 90° C (Wishart and Craigie, 1936).

Certain authors, apart from Craigie and his coworkers, have isolated heat-stable antigenic components from vaccinia-infected tissues

Smith (1932) has isolated a thermostable substance from extracts of a testicular strain of vaccinia which he suggests is the same as Craigie's factor Salaman (1934)

[1] References are appended at the conclusion of Ch XXXV, p 403 et seq

and Rule, 1946; Fasquelle, 1947). Gohar and Bashatli (1946), however, claimed that if rabbits were treated with penicillin shortly after inoculation, only trivial lesions appeared.

Groupé and Rake (1947) working with eggs demonstrated an antibiotic effect with commercial, but not pure penicillin.

Streptomycin is also useless (Kolmer and Rule, 1946)

THE EFFECT OF CHEMICAL AGENTS ON VACCINIA VIRUS

Numerous chemical agents have been examined for a sterilizing effect on vaccinia virus and the following substances have been found to destroy it in varying times

Hydrochloric acid (N/1,000)	Gordon (1925)
Caustic soda (N/500)	Gordon
Ethyl, and methyl alcohol	Gordon, Yaoi and Kasai (1931 *b*)
Acetone	Gordon, Yaoi and Kasai
Izal and oil of cloves	Gordon
Potassium permanganate (1/100,000)	Gordon
Hydrogen peroxide	Gordon, Yaoi and Kasai
Camphor and thymol	Yaoi and Kasai
Hydroxylamine and hydrazine	Yaoi and Kasai
Sodium amalgam	Yaoi and Kasai
Sodium hydrosulfite	Yaoi and Kasai
Chloroform and ether	Yaoi and Kasai, Duran-Reynals (1928 *b*)
Quinine and optochin	Yaoi and Kasai
Iodine	Noguchi (1918), Yaoi and Kasai
Antiformin (1/10,000)	Yaoi and Kasai
Phenol	Noguchi (1918), Yaoi and Kasai (1930)
Bile	Courtois (1935)
Mercuric chloride	Beattie and Baldwin (1933-4)
Ascorbic acid	Kligler and Bernkopf (1937)
Potassium salicylate	Cooke and Best (1941)
"Liquor antisepticus" and lysol	Dunham and MacNeal (1942, 1942-3)

Though formalin appears to destroy virus, e g, in brain tissue, virus can be reactivated by dialysis or trypsinization (Galli and Vieuchange, 1939 *a*, *b*) However, if the suspension of virus is purified, and freed of tissue, virus cannot be reactivated (Levaditi and Reinié, 1939 *c*, Vieuchange and Galli, 1939 *b*)

Vaccinia is destroyed by glycerol more quickly than is herpes (Levaditi, 1941 *b*, Gohar and Bashatli, 1946)

THE EFFECT OF CERTAIN BIOLOGICAL AGENTS ON VACCINIA VIRUS

1. Beard and Rous (1938) have shown that the infectivity of vaccinia is largely suppressed when it is mixed with suspensions of living Kupffer cells or clasmatocytes, and then injected intradermally Such suppression of infectivity is not, however, due to the production of antiviral substances by these cells, for the virus proliferates in tissue cultures of Kupffer cells

2 Hirano (1931 *b*) found that vaccinia was strongly resistant to trypsin, was not digested by diastase, but was readily digested by lipase Pirie (1935) also found virus to resist trypsin, but it was destroyed by fatty acids and lecithin

3 It has been claimed that in the presence of complement, vaccinial antiserum acts on the virus so as to liberate a toxin, which produces a rash on intracutaneous inoculation of children (Brokman et al, 1930 *a*, Gastinel et al, 1931)

4 Vaccinia is not destroyed by the virus-inactivating agent present in human nasal secretion, or by saponin, or sodium desoxycholate (Burnet, Lush, and Jackson, 1939, Burnet and Lush, 1940)

serum, then flocculation occurs, for here the LS components are in solution (see in particular Craigie and Wishart, 1936 *c*, Wishart and Craigie, 1936). In short, the serological reaction resulting when vaccinial (or variolar) antigen is mixed with

ion occurs
ince; fixa-
tion also occurs between immune sera and elementary bodies (Craigie and Wishart, 1934 *b*, Finlayson, 1935).

Degradation of LS The nature of LS.

investigators now enables us to visualize fairly

covered with S antigen they behave like EB's in electrophoresis experiments, the mobility of EB's corresponds to that found for the S antigen (Shedlovsky and Smadel, 1940, Smadel *et al.*, 1940).

2 Electrophoretic experiments on virus-free filtrates of suspensions of dermal pulp show all LS activity to be associated with a single component This LS antigen precipitates to equal titer with optimal amounts of L and S antibody, and is completely removed from solution by adsorption with either. The LS antigen appears to be a protein with 2 antigenically distinct parts, L and S Heating modifies the L portion, so that it no longer precipitates with L antibody, but this "degraded" antigen still combines with L antibody to inhibit precipitation, it still precipitates with S antibody. This substance is known as L'S.

Treatment with heat and dilute alkali modifies S, so that it combines with S antibody and inhibits precipitation, but this antigen does not precipitate with S

L are
activi-
e sero-

ith the L and S antigens is present in one protein molecule This conception is slightly different from that of Craigie and Wishart, who considered the two antigens as ordinarily occurring in the form of a complex which could be dissociated (Smadel, Lavin, and Dubos, 1940, Shedlovsky and Smadel, 1942, Smadel and Rivers, 1942,

943) studied LS by electrophoresis, and that *LS is homogeneous, and has an iso-* rtial specific volume is 0 72 cc/gm, and its diffusion constant $1\,50\times10^{-7}$ cm²/sec The sedimentation constant is 6 35 at 20° C; the MW is 214,000. L'S and L"S' are homogeneous electrophoretically, but not in the centrifuge, L"S' being very polydisperse.

4 Smadel, Hoagland, and Shedlovsky (1943) found that the LS antigen contains 15 8 per cent N and 50 6 per cent. C, and is of protein nature The produce LS" contains the same amount of N as the native substance, but unlike LS, forms needle-shaped crystals

NP antigen.

Alkaline extracts of vaccinial EB's contain a nucleoprotein antigen present in amounts equivalent to 40–50 per cent. of the weight of EB's This antigen is heat-stable S antisera prepared by immunizing rabbits with heat-inactivated EB's also contain NP antibodies (Smadel, Rivers, and Hoagland, 1942).

2. The Precipitation Reaction

Precipitation (flocculation) can be elicited between vaccinial extracts or Seitz filtrates and antiserum, and early work on this reaction was carried out by various

obtained a similar substance from the skin crusts of dermal vaccinia. Ch'en (1934–5) claims to have isolated a polysaccharide substance which he regards as a haptene and a specific product of the vaccinia virus. Commenting on this work, Craigie and Wishart (1936 *c*) suggest that Ch'en's carbohydrate is a polysaccharide haptene of the S component of the LS antigen.

Parker and Rivers (1937) and Parker (1938 *a*) isolated a stable serologically active substance from tissues infected with vaccinia, which is probably identical with the S factor.

The source of LS antigen.

Most of Craigie and Wishart's work has been carried out with a dermal strain of virus "CL," but other strains, including testicular ones, can yield the LS antigen.

LS antigen is demonstrated most readily in suspensions of dermal pulp, prepared in the rabbit, calf, or guinea-pig (Craigie and Wishart, 1935); it occurs also in testicular pulp, and has been found in virus grown in tissue culture (Ch'en, 1934–5), and in the fertile egg (Smadel and Wall, 1937). Although LS is so readily demonstrated i [illegible] or whether it [illegible] necessary to demonstrate its presence (Craigie and Wishart, 1936 *c*).

LS antigen also dissociates from elementary bodies *in vitro;* the elementary bodies are still highly infective after this dissociation ceases (Craigie and Wishart, 1936 *b*). Further, these authors reported that elementary bodies dissociate 20 to 50 times less LS than does the volume of fresh pulp from which they are prepared.

Craigie and Wishart (1936 *b*) discuss the question whether the L and S antigenic components are produced within the virus particles, or whether they are formed outside. If the latter, it may be by the interaction of substances secreted by the virus with constituents of the infected cell. As elementary bodies dissociate much less LS than does the vaccine pulp from which these elementary bodies are prepared, they suggest that vaccinia virus exists in two forms. First, resting elementary bodies in which the metabolic activity is very low (see also p. 338), here there is little dissociation of LS. Second, in the intracellular or rapidly proliferative form, where there is much dissociation, they suggest that LS is elaborated by the virus in its active form. When the elementary bodies are separated from the cells, then LS is adsorbed on their surface and is not dissociated.

Additional evidence that LS is formed from the virus itself, and not from the host as was tentatively suggested by Sabin (1935 *b*), is afforded by the demonstration of LS in so many sources (*vide supra*).

Preparations of LS antiserum

It has been found that sera prepared in rabbits by inoculation of partly purified elementary bodies, or of Seitz filtrates of lapine, contain 2 agglutinins, acting on the L and S antigenic components respectively (Craigie, 1934, Craigie and Wishart, 1934 *a*, 1936 *c*, Wishart and Craigie, 1936).

Specific sera, to react only with either the L or the S antigenic factors, have also been prepared, and used to titrate the content of various vaccinial preparations in these components (Craigie and Wishart, 1935).

Both L and S antibodies are concerned in the agglutination or flocculation of vaccinial elementary bodies or extracts.

The rôle of LS in the serological reactions of vaccinia.

Both the agglutination and flocculation tests (described below) are dependent on the interaction of LS antigen and antibody. If pure washed elementary bodies, free of all flocculable substances, are treated with antiserum, then agglutination occurs. In this case the antigenic components are adsorbed on the surface of the elementary bodies. However, if a suspension of vaccine pulp is treated with anti-

serum, then flocculation occurs, for here the LS components are in solution (see in particular Craigie and Wishart, 1936 c, Wishart and Craigie, 1936). In short, the serological reaction resulting when vaccinial (or variolar) antigen is mixed with antiserum depends on the physical state of the antigen

1934 b, Finlayson, 1935).

Degradation of LS: The nature of LS.

Work by an American group of investigators now enables us to visualize fairly clearly the nature of the LS antigen

1. When collodion particles are covered with S antigen they behave like EB's in electrophoresis experiments, the mobility of EB's corresponds to that found for the S antigen (Shedlovsky and Smadel, 1940, Smadel *et al.*, 1940).

2 Electrophoretic experiments on virus-free filtrates of suspensions of dermal

with S antibody This substance is known as L'S

Treatment with heat and dilute alkali modifies S, so that it combines with S antibody and inhibits precipitation, but this antigen does not precipitate with S

These experiments indicate that all the serological activity associated with the L and S antigens is present in one protein molecule This conception is slightly different from that of Craigie and Wishart, who considered the two antigens as ordinarily occurring in the form of a complex which could be dissociated (Smadel, Lavin, and Dubos, 1940, Shedlovsky and Smadel, 1942, Smadel and Rivers, 1942, Smadel, Hoagland, and Shedlovsky, 1943)

3. Shedlovsky, Rothen, and Smadel (1943) studied LS by electrophoresis, and in the analytical centrifuge They found that LS is homogeneous, and has an isoelectric point at pH 4.8 At 4° C the partial specific volume is 0 72 cc/gm, and its diffusion constant $1\ 50 \times 10^{-7}$ cm²/sec The sedimentation constant is 6.35 at 20° C; the MW is 214,000 L'S and L"S' are homogeneous electrophoretically, but not in the centrifuge, L"S' being very polydisperse

4. Smadel, Hoagland, and Shedlovsky (1943) found that the LS antigen contains 15 8 per cent. N and 50 6 per cent. C, and is of protein nature. The produce LS" contains the same amount of N as the native substance, but unlike LS, forms needle-shaped crystals

NP antigen.

Alkaline extracts of vaccinial EB's contain a nucleoprotein antigen present in amounts equivalent to 40–50 per cent of the weight of EB's. This antigen is heat-stable S antisera prepared by immunizing rabbits with heat-inactivated EB's also contain NP antibodies (Smadel, Rivers, and Hoagland, 1942).

2. The Precipitation Reaction

Precipitation (flocculation) can be elicited between vaccinial extracts or Seitz filtrates and antiserum, and early work on this reaction was carried out by various

persons (Tanaka, 1902, Freyer, 1904, Tomarkin and Suárez, 1917, Torikata, 1917, Havens and Mayfield, 1931). Of special interest, in view of later work on the S and other heat-stable substances, was Torikata's demonstration that a boiled filtrate of calf lymph contained a heat-stable antigen that stimulated the development of precipitins on injection. Tomarkin and Suárez also stressed the value of heated extract in eliciting the precipitin reaction.

Recent work (see above) has shown that the flocculation reaction with crude suspensions is dependent on 2 distinct factors. First, a precipitin reaction with vaccinial antigen in solution; and second, an agglutination reaction in which the elementary bodies only are concerned. The rôle of the LS antigen in this reaction has already been discussed The precipitin reaction is of great value in the diagnosis of smallpox and is discussed elsewhere (see end of chapter).

3. The Agglutination Reaction

The injection of elementary bodies, or cruder virus-containing suspensions, into rabbits stimulates the development [illegible] hen, 1913, 1924, Ledingham, 1931, 1932, 1933, Parke [illegible] (1932), for instance, showed that if rabbits were [illegible] he shaved back, then agglutinins for elementary bodies developed in the serum.

Craigie (1933) showed that when previously vaccinated rabbits were inoculated with killed elementary bodies, there was an increase in agglutinins similar to that produced by living elementary bodies. He found that elementary bodies washed free of the flocculable substance could be used to yield an antigen for macroscopic tests when diluted 1, 20 to 1/50

It has been calculated that 1.95×10^8 particles per c c of suspension are needed to produce visible agglutination (Parker and Rivers, 1936 *b*).

Recent work has shown that the LS antibody in antivaccinial serum acts on the LS antigen to cause agglutination.

4. Inhibitory Effects in the Precipitation and Agglutination Reactions

Craigie (1932 *b*) studied these effects and reported as follows·

(*a*) The agglutination of vaccinial elementary bodies by immune serum at 50° to 55° C. is interfered with if fresh serum is used. Normal serum exerts a similar inhibiting effect.

(*b*) A similar inhibition affects the Seitz filtrable flocculable substance in the precipitin test

(*c*) This inhibiting effect is developed in fresh serum when heated by itself for 5 to 10 minutes at 56° C. It is also developed when fresh serum and antigen are incubated together at the same temperature.

(*d*) Immune serum to be used in agglutination and precipitation tests must be heated alone at 56° C. for 45 minutes to destroy this inhibitory effect.

(*e*) The inhibitory effect is not destroyed if antigen and serum are heated together at 56° C, even for 16 hours

5. The Complement Fixation Reaction

Many authors have shown that complement may be fixed by vaccinial lymph or infected tissue extracts in the presence of immune sera (Jobling, 1906, Beintker, 1908, Kolmer, 1916, Gordon, 1925, Gildemeister and Heuer, 1927 *b*, Bedson and Bland, 1929 *b*, Gilmore, 1931, Nakajima, 1932, Thompson, Hazen, and Buchbinder, 1932, Parker and Muckenfuss, 1933, Parker, 1934, Myers and Chapman, 1937, Weil and Gall, 1940, Rice, 1946)

Various materials may be used as a source of antigen in the complement fixation test, for example vaccinial dermal lymph, suspensions of infected testis, or brain (fresh, desiccated, or glycerolated), cocto-antigen, suspensions of infected

chick chorio-allantoic membranes, infected tissue cultures, and variolar vesicle or pustule contents. It has also been shown that complement is fixed by the interaction of antiserum with the elementary bodies or the Seitz filtrable moiety of vaccinia (Craigie and Wishart, 1934 *b*, Finlayson, 1935).

Complement fixing antibodies usually appear within 7 to 10 days of infection and persist for several months. The test is used in the serological diagnosis of smallpox, and further descriptions are given at the end of the chapter.

6. The Virus Neutralizing Test

It appears that normal whole blood or serum has some degree of virus neutralizing action (Douglas and Smith, 1930, Ramon *et al.*, 1942 *a*).

A number of workers has demonstrated that the sera of immunized animals and convalescent cases of smallpox or vaccinia have a neutralizing effect *in vitro* on preparations of virus (Sternberg, 1892, 1896, Béclère, Chambon, and Ménard, 1899, Camus, 1908, 1909, 1917, Kelsch *et al*, 1908, Teissier and Gastinel, 1912 *b*, Gins, 1916 *b*, Sato, 1921, Matsuda, 1924, Gins and Iwanoff, 1928, Schultz, Bullock, and Lawrence, 1928, Yaoi, 1935 *a*, 1937, Plotz, 1938 *c*). Gordon (1925) showed that the antibody was stable at 55° C, and that complement was not necessary. Béclère, Chambon, and Ménard (1899) showed that antibody was associated with globulin

The virus neutralizing antibody usually appears a few days after inoculation in rabbits, and may persist for 2½ years, longer than the duration of agglutinins or precipitins (Morgan and Olitsky, 1940). Thompson and Buchbinder (1931) detected a well-marked correlation between the titers of the flocculating and virus neutralizing antibodies, on occasions, however, the neutralizing antibody titer might be high while the flocculating titer was low Other workers have also drawn attention to a lack of correlation between neutralizing and agglutinating antibodies (Levaditi and Reinié, 1939 *b*, Levaditi *et al*, 1940 *b*).

Virus neutralizing antibodies can be titrated in various ways Haagen (1936 *a*) injected serum-virus mixtures cerebrally in mice (see also Bronson and Parker, 1941). Antibodies can be titrated by reduction in the number of vaccinial or variolar lesions produced on the chorio-allantois (Keogh, 1936, Blattner, Heys, and Gol- [illegible] *b*). Alternatively, serum-virus mixtures may [illegible] it's back (Loutit and McClean, 1945). Led- [illegible] have both devised methods based on rabbit titration.

Salaman (1938) believes that, under constant conditions, a given quantity of antiserum inactivates a constant percentage of any dose of virus upon which it acts Parker (1939) found that when the concentration of serum is held constant, the quantity of virus neutralized depends on the amount added Further, the proportion of virus neutralized by a given concentration of serum increases as more concentrated suspensions of elementary bodies are used. When the immune serum is diluted, the serum becomes relatively more efficient in neutralizing the virus, although the actual quantity of virus neutralized is diminished.

7. The *in vitro* Interaction between Vaccinia Virus and Antiserum

As has been stated, virus neutralizing antibodies can be demonstrated readily in immune sera The important question arises as to the state of the virus in serum-virus mixtures that appear neutral, for example, on application to the rabbit's skin Numerous workers have demonstrated the presence of active virus in such supposedly neutral mixtures, using the following methods for reactivation

Injection of a mixture, apparently neutral when injected dermally, into a more susceptible tissue such as brain, testis, or chorio-allantois (Andrewes, 1928, Lépine, 1930, Fairbrother, 1932, Myers and Chapman, 1937, Vieuchange, 1938 *b*, Vieuchange and Mesrobeanu, 1938)

Filtration (Andrewes, 1928, Sabin, 1935 *a*)

Adsorbing with kaolin (Andrewes, 1928, Goyal, 1935).
Simple dilution (Andrewes, 1928; Long and Olitsky, 1930, Goyal, 1935; Keogh, 1936).
Cataphoresis (Lépine, 1930, Long and Olitsky, *1930*).
Centrifugation (Sabin, 1935 *a*, Magrassi and Hallauer, 1936).
Addition of testicul[illegible]
However, even in [illegible] that some portion of the virus had been [illegible] ..longed interaction, a specific union does occur, *and that virus* and serum cannot then be readily dissociated (Andrewes, 1930, McKinnon, 1930; Craigie and Tulloch, 1931; Gilmore, 1931; Fairbrother, 1932; Vieuchange and *Stamatin, 1938*).

8. Allergy

The skin of animals becomes allergic on recovery from infection, and responds to reinoculation by an accelerated *reaction (see, e g,* Thompson, 1930 *b*, Dienes and Naterman, 1937; Plotz, 1938 *c*; Levaditi *et al.*, 1940 *a*) Henseval (1919 *a*) found that no allergic response was elicited on reinoculation if the area of primary infection *was excised after* 3 days, when it was excised after 6 days, a typical allergic response developed on revaccination. Force and Beckwith (1915) noted a severe reaction *when vaccinia*-infected rabbits were inoculated with variolous material.

Sensitization may be induced by inoculations of killed vaccinia (Gastinel and Fasquelle, 1943 *c*).

The allergic response has been elicited by a reinoculation of boiled (variola) virus (Blaxall, *1923*). Buchbinder (1932) could not demonstrate any specific contraction of the uterine muscle of sensitized guinea-pigs when exposed to vaccinia *in vitro*.

The state of allergy may develop independently of resistance to vaccinial infection, e g, after sensitization induced by killed virus (Gastinel and Fasquelle, *1943 a, c*).

9. The Preparation of Antivaccinial Sera

Antivaccinial sera, for use in serological tests, or for conferring passive immunity, are usually prepared by repeated injections of rabbits with virus Antisera to the L or the S antigenic components can be separately prepared, but sera obtained by inoculation of partially purified elementary bodies or vaccinia-infected suspensions contain both of the antibodies. Representative methods are described in detail elsewhere (see p 371). Immune sera have also been prepared by injection of horses (Béclère, Chambon, and Ménard, 1899, Ledingham, Morgan, and Petrie, 1931, Bridré and Bardach, 1938, Cesari and Boquet, 1938, Ramon, Boquet, and Richou, 1942, Ramon *et al*, 1942 *b*), buffaloes (Pandit *et al*, 1931–2), goats (Yaoi, 1935 *a*, 1936 *b*), and guinea-pigs (Bedson and Bland, *1929 b*).

Findlay (1931) found that in antivaccinial rabbit sera the immune body responsible for the protective action, flocculation, and action stimulating the "phagocytosis" of virus was associated with the globulin

In the method described by McKinnon and Knowles (1931) the virucidal antibody was obtained in approximately fivefold concentration in the pseudoglobulin, the euglobulin containing only a small amount.

Antivaccinial serum may be titrated most easily by estimating the virus neutralizing antibody (p. 363)

Site of production of immune bodies Only a few observations bearing on this point have been reported For example, the importance of the spleen has been suggested, as it has been claimed that immune bodies develop in tissue cultures of spleen infected with vaccinia (Kimura and Fujisawa, *1931*)

The rôle of the reticulo-endothelial system was investigated by Mundel and Zurukzoglu (1935), who found that virucidins appeared more quickly in the sera

of rabbits in which "blockade" had been carried out with trypan blue than in controls.

McMaster and Kidd (1937) have shown that an antiviral substance is produced in the regional lymph glands which drain the area of skin injected with virus For example, after inoculation of the skin of the rabbit's ears, virus was carried to the regional nodes, and an antiviral substance could be demonstrated in a few days in greater concentration in the nodes of the injected side than in the serum. After inoculation in the skin, virus neutralizing antibody may be produced locally (Vieuchange and Galli, 1939 *a*, Hartley, 1940, Vieuchange, 1940).

Extracts of spleen, lymph glands, and testes of immunized animals neutralize vaccinia virus (Douglas and Smith, 1930, Vieuchange, 1937).

10. Antibody Absorption

It has been shown that vaccinial antigen can absorb specific antibody from immune serum.

1. For instance, Gordon (1925) showed that flocculating antibodies could be absorbed from antiserum by saturation with vaccinia virus. He found that this treatment removed antibody for both vaccinia and variola

2. Smith (1930) showed that an emulsion of vaccinia-infected testis removed homologous antibody from immune serum further, if the testis emulsion was heated at 58° C. to 60° C. for 1 hour, the power of absorbing antibody was greatly reduced

3 Salaman (1937) has carried out experiments on the absorption of immune sera, with the following results

(*a*) Absorption of antiserum with elementary bodies removes all virus neutralizing antibody, but absorption with specific precipitating substance does not.

(*b*) Absorption with elementary bodies removes all agglutinins, but not all precipitins. Absorption with specific precipitating substance removes all precipitins, but not all agglutinins.

(*c*) Virus neutralizing power, but no agglutinin or precipitin, may be found in certain sera obtained 3 to 4 months after vaccination. This virus neutralizing antibody can be absorbed by elementary bodies, but not by specific precipitating substance.

4. S antibody can be absorbed from LS antisera by treatment with heat-stable vaccinial extracts (Parker and Rivers, 1937).

11. Passive Immunity

Various observers have shown that injections of antiserum given shortly before virus, or in certain cases up to 2 days later, may prevent or modify a local or generalized vaccinial infection, the serum may be injected intravenously, subcutaneously, or at the site of virus inoculation, rabbits, mice, and monkeys have been used (Raynaud, 1877, Hlava and Honl, 1895, Béclère, Chambon, and Ménard, 1896, Camus, 1912 *a*, *b*, Gordon, 1925, Hunt and Falk, 1927, Andrewes, 1929, Craigie and Tulloch, 1931, Ledingham, Morgan, and Petrie, 1931, Pandit *et al*, 1931–2, Yaoi, 1935 *a*, 1936 *b*, Schultz and Hartley, 1936, Andersen, 1937 *b*, Iguchi, 1939 *b*, Vieuchange, 1939 *a*, *b*, Green and Parker, 1942)

It has been claimed that maternal immunity can be transmitted to the offspring (see, e g, Sato, 1921, Nelson, 1932, 1934, Andersen, 1937 *c*).

Nelson (1932) concluded that in the pig the placenta was largely impermeable to protective substances, which were probably transmitted by the colostrum Later (1934), he found that the immunity acquired by sucklings began to wane during the 2nd month, and was almost absent at the end of the 3rd.

Andersen (1937 *c*) studied this question in the young of rabbits which had been vaccinated before pregnancy He found that the young showed virus neutralizing serum antibodies 24 to 48 hours after birth, and that these persisted for at least 3

weeks Correspondingly, these animals were resistant to vaccination from 24 hours to 3 weeks after birth After about 3 months he found that both resistance to infection and antibodies were no longer present. He believed that the state of resistance was directly dependent on the passage of antibodies to the offspring from the mother.

12. Active Immunization

With living virus.

Monkeys become resistant to reinoculation on recovery from infection with variola or alastrim (see, e.g, Horgan and Haseeb, 1939), and the same has been reported for mice (Nelson, 1940 *a*).

It has, of course, been known for a long time that on recovery from vaccinial infection, experimental animals become immune to reinfection. Animals may be immunized by applying living virus to the scarified skin, by inoculating it intra- or sub-cutaneously, or by intraperitoneal injection. The intravenous route, in distinction to the dermal, has been especially recommended for the immunization of rabbits (Kelsch, Camus, and Tanon, 1908, Teissier, Duvoir, and Gastinel, 1912, Camus, 1915, 1916, Myers and Chapman, 1937) It was, in fact, realized early that, to produce immunity, it was not necessary for an eruption to follow the immunizing injection (see, e.g., Raynaud, 1878, Béclère, Chambon, and Ménard, 1898, 1899) Immunity can also be produced by intracerebral, intra-ocular, intratracheal, and intrapulmonary injection, and by instillation of the external auditory canal, conjunctiva, and nose (Calmette and Guérin, 1901, Gordon, 1925, Gins, 1929). Subcutaneous injection in the chin has been specially recommended in rabbits (Yaoi and Arakawa, 1939 *b*)

Resistance to intracutaneous injection is most readily acquired, being usually evident after the 4th day, and pronounced after 10 days, after 100 days the immunity is very much reduced, although some degree may persist for 3 years (see e g, Camus, 1915, Gordon, 1925, Morgan and Olitsky, 1940) It is more difficult to immunize rabbits against infection by routes such as the cornea, testis, or brain, and for this purpose large and repeated doses are usually required Nevertheless, certain workers have reported that resistance to cerebral challenge may develop quickly, even in 4–6 days after dermal or other inoculation (Levaditi and Nicolau, 1923 *a*, Rivers, Sprunt, and Berry, 1933, Levaditi *et al*, 1939 *c*, Gastinel and Fasquelle, 1943 *b*) Mice have also been rendered resistant to cerebral challenge by injections given cerebrally, nasally, or subcutaneously (Iguchi, 1939 *a*, *b*, Bronson and Parker, 1944)

With physically or chemically inactivated virus.

Numerous experiments have been carried out using inactivated preparations of vaccinia virus Immune bodies and resistance to infection develop after such inoculations

(*a*) *Using heated virus* Various investigators have experimented with the effect of heat on the antigenic potency of vaccinia (see, e g, Supfle, 1909, Knoepfelmacher, 1915, Henseval, 1919 *a*, Murata, 1924, Nakagawa, 1924 *a*, *b*, 1925, Gordon, 1925, Hunt and Falk, 1927, Bland, 1932, Kligler and Bernkopf, 1935–6, 1937) Resistance to infection can be produced by injection of virus heated to not more than 65° C. Torikata (1917), however, claimed to have induced immunity with boiled antigen

(*b*) *Using chemically inactivated virus* A number of workers has tested the effect of *formol* on the immunizing quality of vaccinia Hilgers (1931–2) found that formol-inactivated virus was most erratic and not to be relied upon to produce immunity Many other workers claim, however, to have immunized rabbits successfully with formolized virus (Hunt and Falk, 1927, Iwanoff, 1927, Kraus, 1929–

30, Craigie, 1934, Kligler and Bernkopf, 1935–6, Bernkopf and Kligler, 1937; Weil and Gall, 1940). Bland (1932) found that rabbits were difficult to immunize, whereas guinea-pigs were more readily rendered resistant

Parker and Rivers (1936 *a*) carried out an important study with formol-inactivated elementary bodies. Their results were as follows (1) Antibodies, and a temporary degree of resistance to infection, can be produced in rabbits by several injections of elementary bodies rendered inactive by 0 3 per cent. formol. (2) Small repeated doses of elementary bodies are more efficient than single doses of larger amounts (3) The antigenic power of elementary bodies is almost completely destroyed by 10 per cent. formaldehyde or boiling for 2 hours

Phenol-treated virus has also been used for active immunization Gordon (1925), for example, found that phenolated virus provoked resistance to infection, and after a lapse of 100 days this was equal to that stimulated by living or attenuated virus Kraus (1929–30) also claims to have protected rabbits following injections of carbolized lymph Bland (1932) found that guinea-pigs were more readily immunized than rabbits Bigheri (1931), however, was not able to immunize rabbits by phenolated virus

Virus rendered noninfective by bile is still antigenic (Levaditi *et al*, 1940 *b*). Large doses of EB's inactivated with 50 per cent. alcohol are slightly antigenic (McClean, 1945).

(*c*) *Using physically treated virus* Vaccinia treated with ultraviolet light, alpha rays of radon, or supersonic waves is still antigenic (Kasahara and Ogata, 1939, Levaditi *et al*, 1940 *b*, Levaditi and Pérault, 1943).

The development of antibodies. Various workers have noted the development of antibodies after vaccination with inactivated virus Craigie (1934) carried out studies on the development of immune bodies after the inoculation of elementary bodies inactivated by heat, ether, or formol The elementary bodies used for inoculation were washed free of specific precipitable substance. In rabbits inoculated intravenously with these killed elementary bodies, agglutinins developed after the first injection, but no complement fixing properties until 2 to 3 had been given, and precipitins not until 3 were given He noted that formolized elementary bodies produced qualitatively a greater antibody response than heated elementary bodies, or living virus Subcutaneous or intradermal inoculation of formolized elementary bodies provoked poor antibody response.

Parker and Rivers (1936 *a*) found that the development of precipitins and agglutinins did not run parallel with that of neutralizing antibodies. Further, the development of antibodies did not necessarily indicate that the animal was strongly resistant to reinfection

Scalfi (1938) found that immune bodies to vaccinia developed on inoculation of splenic tissue from an infected animal, although this tissue contained no virus

With serum-virus mixtures.

It has been shown that mixtures of virus plus serum, although noninfective on intradermal inoculation, may nevertheless induce immunity, these injections may be given intradermally, by nasal instillation, or subcutaneous injection (e.g, Craigie and Tulloch, 1931, Findlay and Hindle, 1931, Rhoads, 1931). Fairbrother (1933) showed that a considerable resistance to infection might develop after intracerebral injection of mixtures of virus and antiserum that appeared to be noninfective intradermally (see also Iguchi, 1939 *b*)

By other means.

Duran-Reynals (1931) found that animals kept in the same room as those used for

stra

trates no immunization resulted. Yamada (1940) also claimed that virus-free filtrates were antigenic.

Armstrong (1932) claimed that mice immunized with diphtheria toxoid showed less severe reactions after intracerebral injection of vaccinia than did untreated animals. He also (1935) found that irritation of the rabbit's conjunctival sac by instillation of diphtheria toxin rendered the eye relatively resistant to infection with vaccinia.

13. The Mechanism underlying Resistance to Vaccinial Infection

The rôle of antibodies.

It is known that one of the properties of vaccinial antiserum is to cause a neutralization of virus, although it is questionable how stable a union is formed between serum and virus. Further, passive immunity can be conveyed by injecting vaccinial antisera into experimental animals (*vide supra*). It would thus seem probable that humoral immunity plays some part in the mechanism of resistance to infection. Andersen (1937 *c*) has supported this view from a study of neutralizing antibodies and resistance to infection in the young of vaccinated rabbits, he concluded that resistance was directly associated with serum antibodies

Magrassi and Muratori (1937), however, have published observations which tend to emphasize the relative unimportance of virus neutralizing serum antibodies They immunized rabbits by intradermal inoculations of virus plus antiserum, and found that virus neutralizing antibodies developed, and that the animals resisted injections into the skin, testis, or brain. Now, if the animals were immunized with formolized virus, very little resistance to reinfection was produced, but the virus neutralizing antibodies appeared, sometimes to as high a level as in animals treated with the virus-serum mixtures. They suggested that in the case of animals injected with the mixtures a latent infection developed, which had the effect of stimulating the appearance of tissue antibodies. After injections of formolized virus, however, no such latent infection developed, and although antibodies reacting *in vitro* could be demonstrated, true tissue immunity could not (see also Magrassi, 1937, Magrassi and Gregori, 1937).

The rôle of leukocytes.

Various authors have attributed some action to the leukocytes in the defense mechanism against vaccinia (Long and Olitsky, 1930, Fairbrother, 1933, Sabin, 1935 *c*) Fairbrother, for example, showed that immune blood had greater neutralizing properties than immune serum, he suggested that phagocytosis was an important defense mechanism of immune animals, as the effect of serum was enhanced by the addition of leukocytes.

Sabin showed that leukocytes may remove virus from the circulation although they may not destroy it

The persistence of virus in the immune animal.

Much interest was aroused by certain observations of Olitsky and Long (1929), who claimed to have recovered active virus by cataphoresis from the testes of animals long since convalescent from a cutaneous vaccination They suggested that resistance to vaccinia was connected with the persistence of virus in the body, and that there was no immunity without such persistence These results did not, however, receive confirmation at the hands of Herzberg (1931 *a*) or Pearce (1940)

The rôle of the cell.

Apart from any acquired insusceptibility, there is no doubt that some cells have an inherent degree of resistance to vaccinia virus, for example, larger numbers of EB's are needed to infect by the skin than by the brain

There appears to be some evidence that a local immunity can be developed in vaccinia. Thus, Camus (1912 *a*) found that the cornea could be immunized by instillation of antiserum in the conjunctival sac Immune corneae cannot be infected readily with vaccinia in tissue culture (Rivers, Haagen, and Muckenfuss, 1929 *c*) The question has been complicated by the finding of Stoel (1930–1) that although immune testis could be infected in tissue culture, immune spleen could not, he attributed this to the presence of macrophages and leukocytes in the splenic cultures Nevertheless, Florman and Enders (1942) found that virus multiplied in tissue cultures of monocytes from an immune rabbit.

Experiments have shown that virus may become fixed to the cells of a tissue culture, but cannot grow, if the culture is prepared with antiserum. If cells are first treated with serum and then inoculated, virus does not grow. It seems that antibody is fixed to the cell, and thus inhibits the entrance of virus, rather than becoming combined with it (Sabin, 1935 *b*, Magrassi and Hallauer, 1936, Vieuchange a
nomenon can be demon-
strated o
1939).

It is
e to vaccinia in the im-
mune an
bably leukocytes are all
concerned. Whatever the mechanism, immune tissue shows only slight changes and virus is rapidly eliminated on reinjection (see, e g , Force, Beattie, and Lucia, 1939).

B. PRACTICAL APPLICATIONS OF SEROLOGICAL REACTIONS IN HUMAN VACCINIA AND VARIOLA

The Precipitation Reaction

Tanaka (1902) showed that precipitation occurred when serous fluid from a case of variola was mixed and incubated with vaccinial lymph Thereafter there was little advance till Gordon (1925) showed that extracts of variolar scabs gave precipitation reactions with vaccinial antisera.

The precipitin test
smallpox by the work
in 1927 there were 152
and were tested for fl
The test was found to be of most value in confirming cases clinically typical, and in establishing a correct diagnosis in doubtful or actually unlikely cases The test was also shown to be of value in the diagnosis of cases of smallpox occurring in Dundee and elsewhere in 1928. The test was remarkably specific, in particular, chickenpox crusts gave a negative result. Tulloch (1934) has published a useful review of the work carried out on the serological diagnosis of smallpox. The technical details of the precipitation test in the diagnosis of smallpox are described at the end of this chapter.

Tomarkin and Suárez (1917) showed that the precipitating antibody developed in human sera after primary vaccination in about 10 days, persisting for a few months After revaccination, the antibody appeared in about 7 days Havens and Mayfield (1931) also recorded the presence of precipitins in the sera of vaccinated persons

Complement Fixation Reaction

Several early workers showed that complement fixation could be elicited using

variolar pustular exudate and variolar sera. Similar results were obtained by other early workers (e g Dahm, 1909, Xylander, 1909, Kryloff, 1911, Teissier and Gastinel, 1912 *a*, *b*, Klein, 1914, Konschegg, 1915).

Kolmer (1916) carried out valuable studies on the complement fixation reaction in vaccinia and smallpox. His results were as follows:

(a) Using scabs and vesicle contents of smallpox patients, he obtained positive fixation with the sera of vaccinated rabbits. This result was later confirmed by Gordon (1925).

(b) Using the sera of persons suffering from mild smallpox, he found that about 60 per cent. gave fixation with vaccinial or variolar antigens.

(c) Complement fixation was also obtained using mixtures of serum from persons previously vaccinated and vaccinial antigens.

It is thus evident both that complement fixing antibodies can be demonstrated in the sera of cases of variola or vaccinia, and that variolar scabs may be used to demonstrate fixation with animal antisera. A number of other workers have arrived at similar conclusions (Gilmore, 1931; Havens and Mayfield, 1932; Venkataraman, 1932–3, Parker and Muckenfuss, 1931–2, 1933, Parker, 1934).

Craigie and Wishart (1936 *a*) have strongly recommended the complement fixation test in variola. They state that the test is 8 to 10 times as sensitive as the flocculation test, and more easily carried out in routine laboratories, 0.008 gm. of clean crusts, or the total contents of 6 lesions, furnishes enough material to act as antigen. The antiserum should contain S antibody. The technique of this test is described in an appendix at the end of this chapter.

Downie (1946) found the CFT with vesicle fluid or crusts the most valuable single test; the material from 6 lesions may be sufficient. He also reported on the value of testing the patient's serum for complement fixing antibodies, using vaccinia antigen prepared in the rabbit, these antibodies may be present after the first week of illness.

The Virus Neutralizing Test

Virus neutralizing antibodies appear in the sera of cases of variola and of vaccinated persons (see, e.g., Béclère, Chambon, and Ménard, 1899, Schneider, 1923–4. Frisch, 1935, Greengard and Wolf, 1940, Blattner, Heys, and Gollub, 1943, Downie and Dumbell, 1947 *b*). They reach a high level about 16 days after the onset of variola (Blattner, Heys, and Gollub, 1943). Serum from vaccinated persons contains maximum antibody in the 3rd and 4th week (Loutit and McClean, 1945). Antibody may persist for a year or so.

APPENDIX

TECHNIQUE OF THE VARIOLA-VACCINIA FLOCCULATION AND COMPLEMENT FIXATION TESTS[1]

In the preparation of these instructions we wish to acknowledge the invaluable assistance of Professor W. J. Tulloch of Dundee, Scotland.

Reagents Required

1. The material to be investigated.
2. Variola, vaccinia, or lapine crusts to serve as a positive control.
3. Varicella crusts to serve as a negative control.
4. Lapine immune serum prepared by hyperimmunizing rabbits with extracts of vaccinia passaged in that animal species.
5. Normal rabbit serum.

The above reagents are required for the flocculation test, and for the complement fixation test the following additional materials are required:

6. Pooled guinea-pig complement.
7. Hemolytic system.

The control reagents, i.e., "2" and "3," are best stored in the form of dried crusts, preferably dried from the frozen state, while the material to be investigated consists either of crusts or of swabs impregnated with the contents of vesicles and allowed to dry.

[1] The CFT is preferred in routine diagnostic work owing to its greater sensitivity and easier technique. The flocculation test is now chiefly of academic interest.

Preparation of Antigen

To prepare an antigen for the tests, quantities up to 40 milligrams of dried crusts are triturated and 0.2 c.c. of 8.5 per cent NaCl solution added.

The crusts are allowed to macerate in this fluid for several hours at room temperature, when 1.8 c.c. of neutral distilled water is added and the extracts centrifuged at high speed for 15 to 20 minutes. The supernatant fluid so obtained represents a 1/50 extract of the crusts and constitutes the antigen. This extract can be suitably diluted for performing the tests.

In the case of swabs, the actual quantity of material available for extraction is, of course, unknown. In extracting these it is advisable that the complement fixation reaction, rather than the flocculation test, be used because of the greater delicacy of the former.

In extracting swabs, 0.2 c.c. of 8.5 per cent NaCl is put in a small tube, and in this the impregnated tip of the swab is extracted, as is done in the case of crusts.

Use of Antiserum containing Antibodies to the S Fraction of Craigie's LS Antigen

In immunizing rabbits for the preparation of diagnostic serum, the immunizing inoculum should consist of extracts that have been heated to 70° C. for 1 hour. This is done to insure that antibody to the S of the LS antigen, obtained from extracts of various material, will be present in the antiserum.

Such sera before use should be titrated against the S fraction of the antigen. This is advisable because the L fraction of the LS complex is unstable, and deterioration of the L fraction may occur in transit. If then diagnostic antiserum potent only in respect of the L fraction were used, false negative reactions would occur when extracts of such "deteriorated crusts" constituted the antigen for the test.

Sera to be used for these tests—both immune serum and normal control serum—should be inactivated by exposure to 56° C. for 45 minutes and stored without preservative.

It may be convenient to dry such sera from the frozen state and store *in vacuo*, if the product is only to be used infrequently, and if danger of contamination is feared. The dried sera are reconstituted when required by dissolving the dried powder in the requisite amount of distilled water. 1 gram of dried serum represents on an average 16 c.c. of the material in its fluid state.

Preliminary Titration of Antiserum

When the antiserum has been harvested it is titrated by the following method.

1/1,000 extract of lapine is prepared and is added to serial dilutions of serum. The range of dilutions of serum distributed is from 1/12.5 to 1/400, doubling the dilution at each tube, the volume being 0.25 c.c. To each of these is then added 0.25 c.c. of a 1/500 extract of lapine crusts, so giving a final range of concentrations of serum from 1/25 to 1/800 tested against an antigen consisting of a 1/1,000 extract of crusts.

An exactly similar series of control tubes with normal rabbit serum is set up at the same time.

The mixtures are kept at room temperature for 2 hours and then transferred to an incubator at 55° C., precautions being taken to prevent evaporation, for 16 hours. The results are then read, using an agglutinoscope to observe the flocculation.

The result of such a test is shown in the following table.

TABLE 13

Final dilutions of crust extract 1/1,000

Final dilutions of serum					
1/25	1/50	1/100	1/200	1/400	1/800
Immune rabbit serum					
++++	++++	++++	++	+	–
Normal rabbit serum					
–	–	–	–	–	–

++++ = marked flocculation easily visible to the naked eye, ++ = flocculation discernible without agglutinoscope, + = flocculation discernible only by agglutinoscope, – = no flocculation.

On this finding the titer of the serum would be accepted as 1/400.

Flocculation Test

In this test the antigens are employed in varying dilutions, while the serum is present in constant concentrations throughout, and the concentration of serum used is 10 times the titer as determined by preliminary examination.

1. Distribution of antigens.

Each antigen is diluted in a series of tubes to give concentrations of 1/125, 1/250, 1/500, 1/1,000 and 1/2,000, the volume per tube being 0 25 c c.

These are set up in duplicate so that to one series immune serum may be added, and to the other normal rabbit serum, to serve as a control

2. Dilutions of sera.

To each of the tubes of one series is now added 0 25 c.c. of immune serum diluted to 20 times the titer· in the case of a serum of the titer shown in the above table, this dilution would be 1/20. To each tube of the second series is added the same volume of normal rabbit serum but of twice that concentration, i e., 1/10

Mixture is insured by shaking, and all the tubes are kept at room temperature for 2 hours, after which they *are transferred to an incubator at 55° C for* 16 to 18 hours, precautions being taken to prevent evaporation.

The results are read in the same way as in the preliminary test shown in the previous table, and it must be emphasized that "zone reactions" are liable to be encountered It is for this reason that series of dilutions of antigens must be tested.

An example of the type of finding to be expected is shown in the following table

TABLE 14

Extracts of crusts tested	Immune rabbit serum final dilution 1/40 Dilutions of crust extracts				
	1/250	1/500	1/1,000	1/2,000	1/4,000
Lapine	+	+	+++	++++	+++
Test material	–	–	+	+++	++
Varicella	–	–	–	–	–
	Normal rabbit serum final dilution 1/20				
Lapine	–	–	–	–	–
Test material	–	–	–	–	–
Varicella	–	–	–	–	–

Complement Fixation Test

The complement fixation reaction is estimated by Craigie and Wishart (1936*a*) to be 8 or 10 times as sensitive as the flocculation reaction Its only disadvantage as compared with the flocculation test is that occasionally extracts of crusts exhibit anticomplementary qualities to an unexpected degree

The reagents are the same as those used in the flocculation test, but in addition complement and hemolytic system are also required.

For this test the complement should cons st of the pooled serum of several guinea-pigs, which is most conveniently prepared by exsiccation from the frozen state, being preserved *in vacuo* in sealed ampules

The hemolytic system consists of a 5 per cent suspension of washed sheep corpuscles sensitized with 5 minimum sensitizing doses of the requisite antiserum

Preliminary Titration of Antiserum

In this, as in the flocculation test, zone phenomena may be encountered Therefore, before being used for diagnostic reactions, immune serum should be titrated by exposing a series of dilutions thereof to a series of dilutions of known positive antigen In so doing, the dilution of antigen should be carried sufficiently far (1/16,000 to *1/32,000) to insure* that negative results are obtained at the lower limit of the series The serum is subsequently used in that concentration with which, in the test performed, the antigen gave

employed to con-

Diagnostic Complement Fixation Test

The hemolytic activity of the complement (m.h.d.) is determined as usual, and the following figures indicate the mixtures of antigen, antibody, and complement which are exposed to one another.

A. In Actual Test each tube contains

1. Antigen serial dilutions from 1/250 to 1/16,000 . . . . . 0.2 c.c.
2. Complement 3 m.h.d. . . . . 0.2 c.c.
3. Serum constant (optimum) dilution . . . . 0.1 c.c.

At the same time controls—"B" and "C"—designed to insure that neither the antigen nor the antiserum are anticomplementary, are put up.

B. Control of Antigen.

1. Antigen in serial dilutions as in A. . . . . 0.2 c.c.
2. Complement 1.5 m.h.d. . . . . 0.2 c.c.
3. Saline . . . . 0.1 c.c.

C. Control of Antiserum

This test is made in duplicate using 2, 1.5, 1, and 0.75 m.h.d. of complement in one series, the antiserum being present in the same concentration as that used in the test, while in the other the same volume of saline is introduced.

The procedure is shown in the following scheme

TABLE 15

Tube Number	*1*	*2*	*3*	*4*	*5*	*6*	*7*	*8*
	c.c.	c.c.	c.c.	c.c.	c.c.	c.c.	c.c.	c.c.
Complement as in test, diluted 1/3	0.4	0.3	0.2	0.15	0.4	0.3	0.2	0.15
Saline	0.1	0.2	0.3	0.35	.	0.1	0.2	0.25
Serum as used in test					0.1	0.1	0.1	0.1

D. Incubation.

Tests and controls are incubated at 4° C. in the cold room for 14 to 16 hours, after which they are set at room temperature for 30 minutes, when 0.25 c.c. of hemolytic system is added to each tube.

The tests are transferred to a water bath at 37° C. and incubated for 30 minutes, when final readings are taken.

In positive reactions some of the range of concentrations of the antigen will give complete fixation of the 3 m.h.d. of complement, while in the cases of controls, lysis should be complete in all tubes containing 1.5 m.h.d. of that reagent.

In their original communication, Craigie and Wishart stress 2 points that are worthy of note

(*a*) The need for incubation at low temperature overnight to insure maximum sensitivity.

(*b*) The employment of the immune serum in concentrations known to give fixation with the stable S fraction of the antigen.

(In describing these diagnostic methods free use has been made of the original contributions of Craigie and Tulloch (1931) and of Craigie and Wishart (1936*a*), to which the reader is referred for further information.)

CHAPTER XXXIV

VACCINATION

Historical

IMMUNIZATION against smallpox originated in the East, where it was known that persons deliberately inoculated with material from a mild case developed a modified form of the disease. This practice of variolization was introduced into England by Lady Mary Wortley Montagu (1689–1762) In England the benefits of variolization were supported by Mead (1747),[1] and in America by the Mathers (see Singer, 1928). This practice was not free from risk, and some patients developed a virulent generalized attack and died. In more recent times, there is a record of leprosy being transmitted (Mora Roldán, 1932).

Sutton from 1764–1766 introduced the safer practice of variolization by arm-to-arm transfer (see McIntosh, 1930).

The next advance was the discovery by Jenner (1798) that material from the lesions of cowpox in man or cows could be inoculated artificially, and induce resistance to variolous material. By 1804 (see *Brit med J*, 1937, *2*, 675), millions of persons had been "vaccinated" with cowpox or "vaccinia" (the 2 viruses then being regarded as identical). Woodville and Pearson, attached to the Smallpox Hospital in London, adopted Jenner's method and vaccinated large numbers of persons by the arm-to-arm method They started with cowpox material, but their stock of lymph almost certainly became contaminated with variola The vaccinial lymph distributed by Woodville to foreign workers was probably chiefly variolous in origin, Jenner himself supplied various foreign observers (see *Med. Phys. J. 3*, *471*, *5*, *340*, *Baron*, *1*, *348*, *439*, *533*)

Vaccination was introduced shortly afterwards into other countries Sweden and Denmark in 1801, India in 1802, Egypt in 1827, following which there was a marked decline in the incidence of the disease

Vaccination Legislation

In England until the introduction of the National Health Service Act, vaccination legislation was governed by the 1898 Act, which although encouraging and making provision for free infant vaccination, contained a clause allowing conscientious objection. There is now no compulsory vaccination in England. The bulk of the lymph required in England was prepared in the Government Lymph Establishment at Colindale, which functioned from *1898–1946* (see *Fremlin, 1946*). Lymph is now prepared at the Lister Institute.

The vaccination laws in America vary from state to state (see Fowler, 1941, U.S Public Health Report, 1941) Investigators in America have canvassed parents to inquire into the incidence of vaccination (Breslow, Shalit, and Anderson, 1943, Gover and Yankev, 1946)

GENERAL PRINCIPLES IN THE PREPARATION OF CALF LYMPH

At a meeting of the Health Organization of the League of Nations at Geneva in August 1928, a number of experts (Aldershoff, Blaxall, Camus, Gins, Gordon, Gorth and Sobernheim) discussed current methods in use for the preparation and preservation of vaccine lymph The recommendations of this *Sub-Commission* were embodied in the text of a report (1928), containing a number of important facts relating to certain general principles involved in the manufacture of lymph, these

[1] References are appended at the conclusion of Ch XXXV, p 403

facts are dealt with below, under their respective headings, together with the findings of certain other workers

1. Origin of Seed Lymph

"Seed lymph" is a term applied in vaccine institutes for the inoculum employed for inoculating calves for preparation of vaccine pulp. The source of lymph used in different institutes varies somewhat, and it has been stated that there is no evidence to show that any difference can be detected in the quality of the lymph prepared from strains of virus originally derived from cases of smallpox or cowpox. However, from time to time the question has been raised of the protective value against virulent variola of vaccine lymph prepared either in distant countries, or from a nonlocal strain of vaccinia It has been felt that to obtain maximum protection against variola, a locally adapted vaccinia strain should be used. There is, however, no convincing evidence to support these views. For example, Horgan and Haseeb (1945) in the Sudan have used a strain of vaccinia deriving from a case of alastrim in London They found that this strain gave excellent protection against variola major. Pandit and Rao (1940) in rabbit experiments found that a recently adapted strain of vaccinia was not a more efficient immunizing agent than a stock institute strain

2. Maintenance of Virulence of the Vaccine Strain by Skin Passage

It is an established fact that the virulence of vaccinia can be maintained over an indefinite period by repeated propagation in calves. The virus is liable to lose its virulence if continuously propagated in the calf alone, and periodical cutaneous passage through rabbits may be adopted in order to exalt its virulence.

Many workers have observed the decline in the immunizing power of vaccine lymph resulting from lengthy passage through the same vaccinifer, and Blaxall (1921), among others, drew attention to this point, likewise, Cunningham (1927) found that after vaccine lymph had been passaged through 6 calves in succession, there was an appreciable decline in the insertion success-rate when tested on children The effect of repeated calf passage on the immunizing power of vaccine lymph has been investigated by Clearkin (1928–9), and Clearkin and Skan (1931), who proved that lymph showed diminished activity in the monkey, whereas lymph which had been propagated alternately between calf and monkey retained its potency (see also Lentz and Gins, 1927).

Another method for exalting the virulence of calf lymph is to passage it through man.

3. Neurolapine and Testicular Lapine

[illegible]

cinated human beings with neurovirus administered subcutaneously without demonstrable ill effects (see also Gonzalez, 1926). It would seem that the objections to the use of neurovirus for human vaccination are more theoretical than practical

TECHNICAL METHODS IN THE PREPARATION OF CALF LYMPH

The methods used in different institutes vary, and full descriptions of some of these are to be found in the publications of Blaxall (1930), Dalal (1930), Stuart and Krikorian (1930), King *et al* (1933), the *Report of the Committee on Vaccination* (1928) and Ducor (1947) We shall give a general account of the preparation of vaccine lymph as carried out in the majority of institutes at the present time

CHAPTER XXXIV

VACCINATION

Historical

IMMUNIZATION against smallpox originated in the East, where it was known that persons deliberately inoculated with material from a mild case developed a modified form of the disease. This practice of variolization was introduced into England by Lady Mary Wortley Montagu (1689–1762). In England the benefits of variolization were supported by Mead (1747),[1] and in America by the Mathers (see Singer, 1928). This practice was not free from risk, and some patients developed a virulent generalized attack and died. In more recent times, there is a record of leprosy being transmitted (Mora Roldán, 1932).

Sutton from 1764–1766 introduced the safer practice of variolization by arm-to-arm transfer (see McIntosh, 1930).

The next advance was the discovery by Jenner (1798) that material from the lesions of cowpox in man or cows could be inoculated artificially, and induce resistance to variolous material. By 1804 (see *Brit. med. J.*, 1937, *2*, 675), millions of persons had been "vaccinated" with cowpox or "vaccinia" (the 2 viruses then being regarded as identical). Woodville and Pearson, attached to the Smallpox Hospital in London, adopted Jenner's method and vaccinated large numbers of persons by the arm-to-arm method. They started with cowpox material, but their stock of lymph almost certainly became contaminated with variola. The vaccinial lymph distributed by Woodville to foreign workers was probably chiefly variolous in origin, Jenner himself supplied various foreign observers (see *Med Phys. J.* 3, 471, 5, 340, Baron, *1*, 348, 439, 533)

Vaccination was introduced shortly afterwards into other countries Sweden and Denmark in 1801, India in 1802, Egypt in 1827, following which there was a marked decline in the incidence of the disease

Vaccination Legislation

In England until the introduction of the National Health Service Act, vaccination legislation was governed by the 1898 Act, which although encouraging and making provision for free infant vaccination, contained a clause allowing conscientious objection There is now no compulsory vaccination in England. The bulk of the lymph required in England was prepared in the Government Lymph Establishment at Colindale, which functioned from 1898–1946 (see Fremlin, 1946). Lymph is now prepared at the Lister Institute.

The vaccination laws in America vary from state to state (see Fowler, 1941, U.S. Public Health Report, 1941) Investigators in America have canvassed parents to inquire into the incidence of vaccination (Breslow, Shalit, and Anderson, 1943, Gover and Yankey, 1946)

GENERAL PRINCIPLES IN THE PREPARATION OF CALF LYMPH

At a meeting of the Health Organization of the League of Nations at Geneva in August 1928, a number of experts (Aldershoff, Blaxall, Camus, Gins, Gordon, Gorth and Sobernheim) discussed current methods in use for the preparation and preservation of vaccine lymph The recommendations of this Sub-Commission were embodied in the text of a report (1928), containing a number of important facts relating to certain general principles involved in the manufacture of lymph, these

[1] References are appended at the conclusion of Ch XXXV, p 403

addition of 2 grains of sodium bicarbonate to a mixture of 79 c.c. of glycerol and 100 c c. of distilled water, to which 0.1 per cent. of oil of cloves is added (Dalal, 1930). The necessity for using a diluent possessing an alkaline reaction, already known for many years, has been stressed by Godinho and von Klobusitzky (1934 *a, b, c*). The pulp is next passed through 2 triturating machines until reduced to a homogeneous consistency, so that the final product is clear in color and uniform in appearance if a loopful is examined with the naked eye against a bright light.

The Bacterial Content of Lymph

According to the *Report of the Committee on Vaccination* (1928), the bacterial content of lymph at glycerolation averages about 4,000 organisms per milligram, consisting mainly of staphylococci, bacteria of the *B mesentericus* and *B. subtilis* group, molds, sarcinae and yeasts (see also Belenky and Popova, 1929 *a, b, c, d*, 1930). These organisms are usually destroyed by the prolonged action of glycerol and oil of cloves during storage at − 11° C, so that after from 3 months to a year the number of bacteria falls to about 5 organisms per milligram, when the lymph may be fit for human use (see p. 378 for details regarding the bacteriological examination of lymph, and p. 379 for tests of potency) Large stocks are held in reserve and are issued in rotation according to demands, the usual age at issue being approximately 2 years from the date of collection. Subject to having passed the requisite tests for sterility and potency, the lymph is supplied for use and is put up in capillary tubes which contain about 0 02 c c., enough for a single inoculation

The comparative resistance of various pathogenic bacteria to the prolonged action of glycerol has been studied experimentally by Godinho (1934 *b*), who observed that if *Br. abortus, Br. melitensis, B. welchii, B. tetani*, staphylococci, *B. tuberculosis*, and gram-negative coliform bacteria were deliberately added to lymph and stored at + 10° C for 1 year, the 3 latter organisms were killed, while the others survived. Menon (1941) confirmed that storage in glycerinated lymph deprived staphylococci of toxicity and power of producing coagulase.

In the case of routine lymph production, the destruction of contaminant bacteria can be accelerated by placing the lymph at + 15° C for 4 to 7 days or even up to 14 days, depending on the retention of potency, or alternatively, by the action of weak antiseptics such as 0 1 per cent. oil of cloves, or 1 0 per cent. ether or chloroform (Dalal, 1930, Greaves, 1938). Numerous methods have been tried for reducing the bacterial content of calf lymph without diminishing its vaccinating properties. Gins (1921), Hackenthal (1930), and Lehmann (1937 *a*) have used carbolic acid as an agent for the destruction of contaminant bacteria in lymph, Gins employing the following method To the raw pulp he added 5 times its own weight of 1 per cent carbolic acid solution, this mixture was thoroughly triturated in a mortar, shaken in a receptacle for 4 hours, centrifuged at 3,000 r.p m. for 30 minutes, the supernatant fluid discarded, and an equal volume of sterile saline added. The last procedure was performed 3 times, in order to free the deposit of phenol, and after the final washing the water containing glycerol (to which agar had been added) was mixed with the deposit, to make up 5 times the weight of the original raw material Martin (1938) recommended the use of Gins's method

Butler (1938) has drawn attention to the value of phenol as an agent for preventing the accidental contamination of lymph He found that lymph, made up in 50 per cent glycerol containing 0 5 per cent phenol, when exposed to − 10° C, + 5° C, and + 15° C for 1 year, retained its potency better than lymph made up after the usual fashion in 50 per cent. glycerol containing 0.1 per cent. clove oil Kaiser (1937 *b*) was able to obtain calf lymph free from bacteria by grinding up the pulp in 0 3 per cent "zephirol," allowing it to stand for 10 hours, centrifuging the suspension, removing the supernatant fluid, and desiccating the deposit. X-rays have been employed by Levin (1935), who claims to have freed vaccine lymph from staphylococci and molds by exposure to the rays, without destruction of the

Seed lymph. This constitutes the stock virus used for regular propagation through calves, it is occasionally passaged through the skin of rabbits in order to maintain its virulence. Only the best and most typical vesicles are selected for seed lymph production, and rabbits are inoculated as follows:

Six to 8 weeks old white-skinned animals are shaved, the skin lightly scarified, vaccinia virus applied with a spatula, and when vesiculation has occurred (48 to 78 hours later), the animals are killed, the skin removed, stretched on a board, and the lesions scraped off with a Volkmann spoon. Material from several rabbits is pooled, weighed, *6 times as much 50 per cent. glycerol in distilled water added, and the* emulsion placed at $-11°$ C in the refrigerator. Such lymph is usually stored for a year or longer, after which it is examined bacteriologically, and if found to be free from pathogenic organisms and of moderately low bacterial content, together with high potency for the dermis of the rabbit, it is diluted 1/3 in 50 per cent. glycerol and used for inoculation of calves Seed lymph derived from calves is likewise treated (see Blaxall, 1930).

Calves. Only the healthiest beasts should be employed for vaccine production Each animal should be carefully selected by veterinary inspection during a period of observation in quarantine which, for lymph institutes in England and Wales, must extend for at least 5 days (Therapeutic Substances Act, 1931), after the vaccine has been collected the animal should be examined postmortem to insure freedom from *any diseased condition, especially tuberculosis Beasts varying from 4 to 6* months can be used.

Preparation of calf. The animal is thoroughly scrubbed with soapy water and antiseptic; the hair over the abdomen and inner side of the thighs is shaved with a razor, care being exercised to avoid cuts or abrasions on the skin; the denuded area is washed in water, dried with a sterile cloth, and 20 per cent. glycerol solution may be rubbed in to preserve the elasticity of the skin. After this treatment the animal is returned to its pen to be inoculated with vaccinia virus on the following day. Ducor (1947) recommends a technique of strict attention to cleanliness, and the use of "Roccal" solution on the skin of the calf; this results in the lymph having a very low final bacterial count.

Method of inoculation. The beast is strapped to a tilting table, is turned upside down, and the shaved area is very thoroughly washed by rubbing the skin for half an hour with soap and water, without the addition of an antiseptic; it is then dried with a sterile cloth, and inoculated with vaccinia virus. This is carried out by dipping the blade of a scalpel in a suspension of stock vaccinia seed lymph, usually diluted in 50 per cent glycerol and [illegible] of about 1 in 24, and then making a series of [illegible] ½ inch apart, these should not be d[illegible] *of the scalpel may then be drawn* [illegible] lymph into the abraded surface, and after the material has dried the animal is returned to its stall For the best results, the lymph should be inoculated in that area of the skin which lies below the malpighian layer and above the rete mucosum Vesicles usually form on the 4th or 5th day, and as these are liable to become dried up in warm climates, Dalal (1930) recommends the application of glycerol at intervals of 48, 72, and 96 hours after vaccination in order to prevent desiccation On the 4th day after vaccination, the rectal temperature rises

Collection of pulp Five days after vaccination the calf is placed on the operating [illegible] skin thoroughly washed with soap and [illegible] Each line of vesicles is then scraped off [illegible] cised in order to avoid, as much as possible, the presence of blood The pulp is placed in a sterile glass receptacle and its weight ascertained, this usually varies from 10 to 30 gm. per calf, and to it is added 4 times as much by weight 50 per cent glycerol in distilled water. The glycerol used has a specific gravity of 1.260, and is rendered faintly alkaline by the

plates and hemolysis in fresh rabbit's blood broth), the lymph is rejected. This is a very infrequent occurrence.

5. If any other pathogenic organism is found, the lymph is rejected.
6. If *B. coli* is isolated either aerobically or anaerobically, the lymph is re-examined (in 0.1 c.c. amounts in broth). If it persists after 3 such examinations at 3-monthly intervals, the lymph is rejected. If it disappears, the lymph may pass.
7. If streptococci other than *S. hemolyticus* are found, the lymph is kept and later reexamined in 0.1 c.c. amounts in serum broth. The lymph is not issued till it is free of such and, by experience, it is very seldom that it has to be rejected for persistence.
8. If hemolytic staphylococci are found, their characteristics are examined (sugars, action on gelatin, serum, and plasma). Because of dubiety as to what constitutes a bacteriological criterion of pathogenicity, it is considered advisable not to issue lymphs containing such in 2 milligrams of lymph, whatever the degree of hemolysis.

If the lymph is now considered satisfactory from the standpoint of bacterial purity and potency, it is put into capillary tubes. The lymph from sample tubes taken at the beginning, middle, and end of tubing is pooled and examined for the 3 criteria laid down by the Therapeutic Substances Regulations (Second Schedule, 1931), Part I (B), viz.

(*a*) Total count must be less than 5 organisms per milligram of lymph. Three separate milligrams are plated.
(*b*) Freedom from the presence of living hemolytic streptococci—smears on an agar plate are examined for streptococci.
(*c*) Freedom from the presence of living gas-producing anaerobic organisms in 0.1 c.c. of the lymph.

The properties of good lymph. These may be summarized as follows: a 0.1 c.c. sample should be free from hemolytic streptococci, hemolytic staphylococci, gram-positive sporing bacteria, and a colony count should yield a result of less than 5 per milligram of lymph.

The German Government regulations regarding the bacteriological examination of vaccine lymph are quoted by Wright (1935).

The Preservation of Vaccine Lymph

Akasawa (1936) stated that the addition of a buffered saturated solution of saccharose to glycerolated lymph enhanced its thermostability. Glue has also been employed as a diluent by Yaoi and Akasawa (1938).

Buddingh (1938*a*) recommended rabbit or ox serum as a protective diluent for calf lymph and also tried, without success, mucin, gum acacia, and egg yolk; suspensions of vaccinia virus purified by adsorption on kaolin were used for vaccination by Yaoi (1936*c*).

Certain workers have achieved a fair measure of success using dried lymph, and it may maintain potency for over a year if dried *in vacuo* from the frozen state; once reconstituted it must be used quickly (League of Nations, 1934; Boulnois, 1936, 1937; Kaiser, 1938; Morosov *et al.*, 1943).

Rabbit Tests for Potency of Lymphs

Under the Therapeutic Substances Act (Schedule 2, 1931) it is decreed that lymph to be used for human vaccination should possess a certain minimum of potency, and the tests advised are the four tests for potency recommended in 1927 by the Smallpox and Vaccination Commission of the League of Nations (see *Report of the Committee on Vaccination*, 1928).

1. *Gins's method.* In this method, a 1:1,000 dilution of lymph should produce

virus. Sonic vibrations were also tried for the purpose by *Yaoi and Nakahara* (1934), but with negative results

Penicillin added to lymph reduces the number of contaminant bacteria (Diaz Romero, 1945, Fasquelle, 1947; Morin and Turcotte, 1947).

Bacteriological Tests for Purity of Calf Lymph

The late Lt.-Colonel W. D. H. Stevenson, in a personal communication to us, recommended the following scheme for the bacteriological examination of lymph Repeated tests are necessary to obviate the risks attached to random sampling of a thick grumous material such as vaccine lymph The scheme is only intended for lymphs not immediately required Immediately after the lymph is prepared, counts for total number of organisms are made by pouring agar plates, and smears of lymph are made on agar plates for the detection of streptococci Then 0 1 c.c lymph is inoculated into Robertson's bullock heart medium under vaseline seal, the tube is heated to 65° C. for 30 minutes to kill nonsporing organisms, and thereafter incubated for 5 days at 37° C. The culture is then examined microscopically, and 0.5 c.c. injected intramuscularly into a mouse with 0.004 gm calcium chloride Also a large drop or large loopful of lymph (unheated) is inoculated into Fildes's blood digest broth, incubated, and from the growth the condensation water of a Fildes's blood digest agar slope is inoculated, this tube, after anaerobic incubation, is examined for the characteristic growth of *Cl. tetani*. After the tests are made, the bulk of the lymph is put into large containers which are not removed from the cold room (approximately − 10° C.) till towards the end of purification. The remainder is put into a small sample container which is brought up, as necessary, for examination. The contents of this small sample tube should be examined for the total counts and the characteristics of the organisms every 3 months When the number of organisms, which may vary from 1,000 to 10,000 per milligram, has fallen in 3 counts to 5 or less per milligram, all the contents of the large containers are examined, and will usually be found to have a considerably higher bacterial content owing to their steady storage at − 10° C If the count is high and the lymph is urgently required, it is incubated from 4 days to 1 week at + 15° C. and reexamined If necessary, a further period of 1 week is given at + 15° C When the contents of the large containers have approximately a bacterial content of 30 organisms per milligram, the lymph from each container is examined in detail. (*a*) Smears are made on agar and blood agar plates to detect streptococci or hemolytic staphylococci (*b*) 0 1 c c from each container is inoculated into Robertson's bullock heart medium The tubes are cooled below 37° C after a preliminary boiling before inoculation, have no vaseline seal but have wide-mouthed Durham tubes, and are incubated for 5 days in an anaerobic jar After 5 days the contents are examined microscopically, and 0 5 c c from each is inoculated with calcium chloride intramuscularly in mice Throughout, when the counts on agar plates are 10 or less colonies per plate, each colony shou[illegible] and, in any case, if streptococci, *B coli* etc, are [illegible] n detail It is recommended that the procedure [illegible] vents should be.

1 If at any stage a gas-producing anaerobe (if gas is not produced solely by the *B coli* group) is found, the lymph is rejected
2 If bacteria possessing terminal spores are found at any stage (the great majority produce gas in the anaerobic tubes in minute quantity) the lymph is rejected This occurs very infrequently
3 If a mouse dies and death is obviously due, or is proved on repeated examination to be due, to the injection of culture, the lymph is rejected. This very seldom occurs.
4 If *Streptococcus hemolyticus* is found (giving *β* hemolysis in blood agar

such tests, "strongly recommended that the medical directors of the vaccine institutes should whenever possible be given an opportunity of themselves undertaking human vaccinations, or at any rate, of satisfying themselves of the success of human vaccinations by personal observation" This is essential in centers where vaccination is not compulsory, and those engaged in the preparation of lymph have to rely on voluntary reports of doctors.

The term "insertion success rate" is applied to the percentage of insertions showing typical primary vaccinial takes when the lymph is inoculated in fully susceptible persons. It should be as near 100 per cent. as possible.

METHODS OF HUMAN VACCINATION

1. Application by Dermal Scarification

Present methods have evolved from the pioneer work of Dimsdale (1767), Bryce (1809), Seaton (1868), and others In Britain it has been recommended in the past that 4 separate insertions should be made, but the effects of this are too severe for general application. The Committee on Vaccination (1928) recommended that. (1) trial be made of vaccination or revaccination in one insertion with a minimum of trauma, and that crosshatching and multiple scarification be deprecated, (2) vaccination in multiple insertions be available for those requiring maximum protection The British Vaccination Order (1930) stated that vaccination should be performed ordinarily by a single linear incision or scratch not more than ¼ inch long, merely through the epidermis, but that under special circumstances up to 4 well-spaced insertions might be used

The skin at the selected site, preferably the left arm over the deltoid insertion, is cleansed with soap and water, and finally with alcohol, ether, or acetone. Some workers omit the chemicals, and in any event the arm must be absolutely dry before commencing to vaccinate. The contents of the capillary tube of lymph are expelled by a rubber teat onto one or more areas of the skin The contents must on no account be blown out, and virulent infection has been traced to this practice A heat-sterilized lancet is then used to make the selected number of scarifications through the lymph. They are usually about ¼ to ⅜ inch long, parallel and well spaced. The papillary layer of the true skin should be entered, and only slight bleeding caused. The lymph may be rubbed in with the lancet, and must be allowed to dry.

A sterile gauze dressing is often applied, but it is a better practice to use none until the lesion vesiculates

Vaccinations should be inspected, at least at the following times after the operation 48 hours, 7 days, 14 days.

2. Application by Multiple Pressure

This method has been particularly recommended by American workers (Leake, 1927, 1930, 1946, Grubbs, 1923), but outside North America has only been used by a few (Dudley and May, 1932, Parish, 1944, Mole, 1947). It is said to give an increase in the number of significant reactions on revaccination A drop of lymph is applied to the skin, and a Hagedorn needle (held parallel to the skin) moved rapidly up and down The trauma is caused by the side of the point of the needle. From 10–30 pressures are made according to circumstances, over an area of skin about ⅛ inch in diameter.

3. Intradermal and Subcutaneous Injection

Many workers have recommended that vaccine lymph, usually diluted, be injected intradermally or subcutaneously (Bussel and Stankiewicz, 1926, Toomey and Hauver, 1928, Kaiser and Hassmann, 1937, Muliner, 1937, Poch, 1938). The benefits claimed for these routes include milder reactions, absence of an "open" ulcer-

vaccinial keratitis in a guinea-pig 72 hours after inoculation of the eye. For this test the ground squirrel has been substituted for the guinea-pig by Goschanskaja and Stschastny (1933).

2. *Sobernheim's method.* Four patches are denuded of hair in a rabbit, and on each patch 3 linear incisions are made 4 cm. long and inoculated with different dilutions of lymph, from 1/1,000 to 1/10,000. The 1/1,000 dilution should show a specific reaction after 3 days.

3. *Gorth's method.* A quantity of 0.1 c.c. of a dilution of lymph varying from 1/10 to 1/100,000 is inoculated intradermally in the shaved skin of a rabbit, the lowest dilution should produce an area of local inflammation and redness in 24 hours' time, and the highest in 4 to 5 days. The size of each area of redness and infiltration can be measured with callipers, and by comparing the relative sizes of different areas it is possible to assess the potency of individual preparations of lymph. The standard recommended by the Commission was an area of redness and palpable swelling following inoculation of 0.1 c.c. of a 1/1,000 dilution of lymph in 72 hours.

4 *a. The Calmette-Guérin method.* In this method 1 c.cm. of vaccine lymph diluted 1/1,000, rubbed over the shaved back of a rabbit, should produce an eruption of 3 to 4 vesicles per sq cm. in 5 days.

4 *b. Blaxall's (1930) modification of Calmette's method.* The back of a rabbit is shaved, divided into 4 areas, and each of these is inoculated with 0 2 c c. of a 1/1,000 dilution of 4 different batches of lymph. Thus, with a lymph diluted to 4 times its original volume, the actual amount of vaccine pulp applied to each area is 1/250,000 gm A confluent eruption of vesicles should form on the 5th day after inoculation, if the vaccine is of adequate potency. In performing the test, care should be taken to scarify the skin lightly before applying the vaccine.

Stevenson (1938) personally informed us that 2 rabbits should be employed for each test, since individual animals vary greatly in their relative susceptibility to vaccinia. The maximum potency of the lymph also supplies valuable information and, therefore, a 1/10,000 dilution of lymph should be inoculated at the same time as the 1/1,000 test is conducted Further data on the examination of calf lymph for potency appear in the extensive report of Stevenson and Butler (1939) on the cultivation of vaccinia virus on the chorio-allantoic membrane of the chicken embryo (see also Force and Leake, 1927).

Issue

After a batch of lymph has passed the requisite tests for bacteriological purity and pathogenicity for the rabbit, it is sealed in capillary tubes and issued for human use Capillary tubes are filled with vaccine lymph by using the Enterican machine.[1] The method is as follows Several tubes, sealed at one end, are clamped in a holder and lowered into a vacuum chamber containing at its foot a quantity of glycerolated calf lymph. As soon as the open ends of the tubing are immersed in the fluid, air is released into the chamber, the lymph flows upwards into the tubes which are thereafter removed, sealed with aseptic precautions, packed and dispatched for use (see also Kaiser, 1937 *a*)

Human Tests for Potency of Lymph

Although lymph which has passed any one of the 4 rabbit tests for potency is fit for human vaccination, it is customary in most institutes to issue a limited quantity from each batch of lymph so that preliminary trials may be conducted on human beings prior to its use among the general population The League of Nations Sub-Commission on Vaccination, referring to the advisability of performing

[1] See Messrs Baird & Tatlock's, Ltd, Catalogue No BP860, p. 1954, Section XXIV, 7th edition.

monkeys and rabbits. Neutralizing antibodies develop to the same titer after inoculation of egg or calf virus and persist for over a year (Buddingh, 1943).

It appears that this method of vaccination may be of the greatest value, and may eventually supplant the older-established methods At the moment, however, there is a natural hesitation to abandon the time-honored method of scarification with lymph, which has been proved effective, beyond any doubt, in controlling smallpox.

7. Vaccination with Tissue Culture Virus

Virus cultured *in vitro* has been used for jennerian vaccination of man by various authors with satisfactory results (Rivers and Ward, 1931, 1933 *c*, 1935, Rivers, 1933, Coffey, 1934, Gallardo, 1934 *a*, Togounova and Baidakova, 1934, Bucher, 1935, Togounova *et al*, 1935, Barg and Borodaj, 1936, Plotz and Martin, 1936, Gallardo and Sanz, 1937, Plotz, 1939, Ellis and Boynton, 1939, Donnally *et al*, 1940).

Elsewhere we describe the technical details involved in the preparation of virus suitable for human inoculation (see Ch. XII). After the intradermal injection of 0 1 c c. of glycerolated culture virus, a small red papule develops in 4 to 6 days, this becomes larger and the zone of induration and erythema measures 2 to 3 cm in diameter (Rivers and Ward, 1935). *Four to 6 days after the beginning of the* reaction, there is noted a secondary less intense area of erythema, which lasts for a few days. Induration lessens progressively and is usually absent 3 weeks from the beginning of the rash Rivers and Ward found that primary vaccination with culture virus produced immunity to revaccination with calf lymph However, it has been found that the state of immunity induced by cultured virus may be of shorter duration than that induced by ordinary lymph (Donnally, 1939)

There are important advantages in the use of tissue culture virus over calf lymph, for it can be inoculated intradermally or subcutaneously, and it can be obtained bacteria-free Further, it is more economical, Herzberg (1932), for instance, found that 1 chick embryo medium (50 c c. bulk) yielded as much vaccine as 8 to 10 calves Culture virus can also be stored quite readily, and virulence maintained

8. Vaccination with Elementary Body Suspensions

Henderson and McClean (1939) inoculated an elementary body suspension intracutaneously, by introducing the needle for 8 mm and producing a wheal at the point of the needle, away from the site of insertion They found there was a definite correlation between the appearance of a typical vesicle following the primary vaccination, and the subsequent development of resistance to revaccination

Gastinel and Fasquelle (1941 *c*) have also vaccinated with EB suspensions

9. Vaccination by Other Methods

Vaccinia may be applied to the nasal mucosa (Gyure, 1939) Virus treated with supersonic waves has been used (Kasahara and Ogata, 1939) Vaccinia grown in culture may be mixed with yellow fever vaccine and applied by scratch (Peltier *et al*, 1939, 1940). Vaccinia and TAB may also be combined and injected subcutaneously (Yaoi, 1939, 1940, Yaoi, Hirose, and Sudzuki, 1939)

It has been recommended that in children at the time of vaccination, diphtheria prophylactic should also be given (Stern, 1935, Iavorschi, 1936).

THE APPEARANCE OF THE PRIMARY VACCINIAL LESION

Three days after vaccination, a small red elevated papule appears at the site On the 5th day, fluid accumulates, and the center of the lesion becomes umbilicated This is the vesicular stage The vesicle extends and on the 8th day appears

ated area, minimal scarring, more accurate assessment of dosage, and smaller consumption of lymph

Subcutaneous injection has been extensively used by Yaoi with bacteria-free lymph (1934, 1935 *b*, 1936 *a*, 1938 *a*, *b*, 1941). Other workers have recommended this route (Gherardini *et al*, 1939, Kaiser, 1939). After this route of injection, an area of infiltration develops between the 7th and 12th days, and this may be accompanied by fever.

Intradermal injection is economical in lymph, as a single tube can be used for about 20 persons, this method has been recommended by a number of workers (Roberts, 1932, Torello-Cendra, 1936, Pierce, 1937, McEwan, 1940, Pottinger, 1940).

Pierce and Willoughby (1943) insert a triangular surgical needle intradermally through a drop of lymph, the needle passing in for 1/16 inch parallel to the skin surface.

These 2 routes of inoculation may be combined (Leiner and Kundratitz, 1921, Simkó, 1925, Rosenbusch, 1936).

4. Vaccination with Virus and Antiserum

Picardo (1931) injected intradermally a mixture of calf lymph and antivaccinial rabbit serum, and claims to have reduced the area of scarring as well as general *malaise*

5. Vaccination with Killed Vaccinia Virus

This has been tried by several workers, but the results as a whole have not been encouraging. Henseval (1919 *b*) found that vaccination with lymph heated to 60° C resulted in a certain amount of protection, but after heating to 70° C. the antigenic property of the lymph was lost Brokman, Bussel, and Mayzner (1930 *b*) also claimed to have vaccinated children successfully using heat-killed or formolized virus, and Bussel and Mayzner (1930) obtained similar results after subcutaneous *or intradermal injection of killed virus*

6. Vaccination with Egg Culture Virus

Vaccine growth in the fertile egg has the following advantages it can be obtained completely bacteria-free, it is relatively simple to prepare, it is cheap, and obviates the necessity for using calves, and this may be a great asset in *the tropics* (Bourguignon, 1936), finally, if at any time there is an extraordinary demand for vaccine, this can be met quickly by inoculating a sufficiency of eggs The originators and leading exponents of this technique have been Goodpasture, Buddingh, and their collaborators in America (Goodpasture and Buddingh, 1933, 1934, Good- [illegible] d in Great Britain (Steven- [illegible] Lehmann (1936 *b*, 1937 *b*, [illegible] in other authors have carried out human inoculation experiments with egg-cultured virus (Godinho, 1934 *a*, *Herzberg, 1935*, Taniguchi *et al*, *1935*, *Munsterer, 1936*, Perini, *1936*, Peragallo, 1936–7, Gallardo and Sanz, 1937, Lazarus *et al*, 1937, Ellis and Boynton, 1939, Gastinel and Fasquelle, 1941 *a*, *b*, Balozet, 1942, Buddingh, 1943, Nagler, 1944)

Elsewhere we describe the technical details of egg passage, and the preparation of vaccine suitable for human inoculation (see Ch XIII) With regard to the results following the use of such vaccine, we may cite certain *observations* For example, Goodpasture and Buddingh (1933) found that, compared to calf lymph, the reaction produced by egg virus was slightly milder, there was less induration and pustulation.

Later, Goodpasture *et al* (1935) claimed that the inoculation of human beings with egg-cultured virus gives as good results as calf lymph, further, *significantly* similar antigenic powers are exhibited by egg virus and calf virus when tested in

1. A reaction reaching its maximum diameter on the 8th–14th day is known as the primary vaccinial response, and occurs in the fully susceptible person (see above).

2. A reaction occurring in those possessing partial immunity, in which the areola reaches its maximum on the 3rd–7th day, is known as the accelerated or vaccinoid reaction.

3. In the immune person, the areola reaches its largest diameter between 8 hours and 3 days. This response is termed the "immune" or immediate.

Incidence of the Various Lesions

The observations of Broom (1947) are of great value, and are shown in Table 16 He performed 1364 vaccinations in adults, mostly revaccinations It will be noted that control reactions to heated lymph occurred in persons revaccinated at intervals of 0 to over 20 years after the last vaccination The relative number of primary takes rose with the lapse of time since the last vaccination, whereas the relative number of immune reactions fell with the passage of time. The proportion of accelerated reactions lay between 40 and 50 per cent. at all periods.

TABLE 16

RESULTS OF 1364 VACCINATIONS AND REVACCINATIONS IN ADULTS (BROOM, 1947)

Years since last Vaccination	*Primary*	*Accelerated*	*Immune*	*Nil*	*Total*	*Control Reactions (Heated Lymph)*
0–2	9	67	64	20	160	14
2–5	15	97	40	43	195	25
5–10	8	48	8	25	89	10
10–15	16	34	0	20	70	8
15–20	25	54	3	30	112	16
>20	213	284	4	100	601	37
Total	286	584	119	238	1227	110
Primary Vaccinations	135	2	0	0	137	—

Technical Considerations in Revaccination

In revaccinating, the lymph used should be of high potency, for lymphs giving satisfactory results in susceptible persons may give indifferent results in semi-immunes (Horgan and Haseeb, 1944 *b*).

Revaccination is usually performed by 2 or 3 insertions, and Horgan and Haseeb found that the advantage of 2 over 1 insertion was very marked.

It is preferable to carry out the insertions in different areas of the skin, for there is some evidence that a local immunity may develop, revaccination of one site may give an unsatisfactory response, but on another area a successful result may be achieved.

A "Successful" Revaccination

This term should be restricted to the primary vaccinial reaction or the accelerated reaction, i e, the appearance of a vesicle should be the criterion of success. These reactions raise the level of immunity, and a person who so reacts may be regarded as protected against smallpox.

The Significance of the Immediate or "Immune" Reaction

[illegible] + to ++++ by the New York Quaran- [illegible] n in the test insertion with an insertion of [illegible] vel of immunity, and it should not be regarded as a "successful" revaccination, failure to understand this point has resulted in a great deal of confusion. Numbers of cases of smallpox have been recorded in

as a firm white swollen lesion On the 9th day, pustulation occurs, and there is a surrounding areola measuring an inch or more. From the 11th day, the pustule undergoes drying, and within the next few days the lesion becomes converted into a scab which eventually falls off, to leave a cicatrix visible usually for life.

According to Regan (1944) the success of a vaccination is indicated by the appearance of a minute white papule with a pink areola appearing within 3–10 minutes of vaccination, and lasting for 20–30 minutes, a hand lens is required.

[illegible]

caused by the presence of fluid, this fluid contains elementary bodies Some intracytoplasmic (Guarnieri) bodies may be found in the cells around the lesion. The contents of the pustule consist of polymorphonuclear leukocytes, a few red cells, fibrin clot, and occasionally secondary invading organisms such as staphylococci, especially if the skin has been abraded through mechanical irritation or scratching The crust or dried scab is composed of desiccated serum and fibrin clot containing disintegrated cells, and the deeper the involvement of the cutis vera, the longer the scar lasts (see Turnbull and McIntosh, 1926). The changes in the epidermis and dermis are said to be much severer in human vaccinia than variola (Howard and Perkins, 1905–6).

Primary vaccination in infants Newborn infants may exhibit resistance to vaccination, this resistance has usually disappeared by the age of 3 months (Schossmann and Herzberg-Kremmer, 1932; Béclerè, 1936). Various views have been put forward to account for this insusceptibility, such as transmission of maternal immunity (see Bennett, 1936; Makgill, 1936), or a natural immunity (Lukacs and Moritz, 1935).

In adults. The general opinion is that adults tolerate primary vaccination less satisfactorily than children, and severe reactions may occur (see Holmgren and Lindstrom, 1937). When a primary vaccinial response occurs in an adult previously vaccinated in childhood the reaction is usually milder (see Gyllensward, 1934, Lindeman, 1934; Halldén, 1937).

USE OF CONTROLS IN REVACCINATION

In order to simplify the interpretation of the response on revaccination, and to distinguish between sensitivity and immunity, it is recommended that at the same time a separate insertion of heated lymph should be inoculated (see, e.g., Hooker, 1925, Broom, 1947, and Table 16).

THE RESULTS OF REVACCINATION

Following revaccination, if immunity induced by the first inoculation has completely waned, a primary vaccinial lesion may develop, and this has been described above. More usually, however, some type of modified response, i e., the immediate or the accelerated reaction, occurs Finally, the revaccination may "fail to take." The interpretation of some of these reactions presents considerable difficulty to vaccinators, and numerous workers have discussed their significance (e g, Leake, 1923, 1927, 1936, 1946, Hooker, 1925, Andervont and Rosenau, 1930, Brokman *et al*, 1930 *a*, McKinnon and Defries, 1931, Bull and Rankin, 1936, Doraisingham, 1940, International Sanitary Convention, 1944, War Office, 1944; Seal, 1945, Mitman, 1947). Particularly valuable discussions that we have consulted are those of Stevenson (1945) and Marsden (1946).

Appearance of the Lesions

Leake defines the reactions as follows, measuring the maximum diameter of the red areola.

sensitization can be effected by repeated injections of killed virus (Gastinel, Reilly, and Mortier, 1932).

SERUM ANTIBODIES IN REVACCINATION

Although there has been a number of studies carried out, there is insufficient evidence to show whether antibody responses can be correlated with the results of revaccination One can only s [illegible] "immune" reactions show the presence of [illegible] (Force *et al*, 1929; Blattner, Heys, and [illegible] glutination-inhibition technique (Ch. XXXI) suggest that a greater rise in antibody occurs after a successful vaccination or revaccination than when an "immune" reaction occurs.

CERTIFICATES OF VACCINATION

Certificates should preferably be given in the form recommended by the International Sanitary Convention (1944) which is reproduced in Fig. 30. It is unfortunate that various bodies fail to accept a certificate of "failure to take," for certain immune persons will not show any other reaction, even on repeated vaccination. It is wiser to adopt the policy of the British Army authorities and give a certificate of "insusceptibility to vaccinia," after 3 attempts to produce a reaction, using multiple insertions, have failed (War Office, 1944)

IMMUNITY TO VACCINIA AFTER VACCINATION

A successful vaccination usually protects against the development of primary vaccinia on revaccination for many years, estimated at from 10–20 or even longer, such previously vaccinated persons tend to develop a modified type of reaction on revaccination (Dudley and May, 1932, Deiring and Rosenau, 1934, Gyllenswärd, 1934, 1936, Reiter, 1935; Loy and Husband, 1938). However, immunity may be much shorter, and Stevenson (1945) quotes a number of cases where revaccination has been performed successfully comparatively recently after the first vaccination There is no definite evidence that these "takes" after short intervals are commoner following vaccination by one insertion, than vaccination by multiple insertions.

The table published by Broom (1947, see above) gives valuable information regarding the likelihood of primary vaccinia developing at varying periods after vaccination

THE VALUE OF VACCINATION AS PROTECTION AGAINST SMALLPOX

The protective power of vaccination (or variolization) against infection with smallpox is one of the best established facts in preventive medicine. The subject can be discussed from 2 angles The ability of vaccination to lower the incidence of smallpox in the community in general, i.e., herd immunity, and the protective power of vaccination in the exposed individual

During and since the second world war, smallpox became a problem to service and other medical officers whose knowledge had hitherto been theoretical rather than practical. Many British and other writers displayed unfamiliarity with the lessons of the past, acquired, for example, at the beginning of this century when smallpox was a serious problem in the British Isles, and taught in particular by Ricketts. Certain authors have done valuable service in restating the true position in regard to the protective powers of vaccination, especially Stevenson (1944) and Marsden (1946)

Immunity in the Individual

No one will question the protective power of vaccination for the individual exposed to smallpox. This is so well attested that it is not necessary to quote extensive references. A striking example is afforded by Marsden's experience in Lon-

soldiers and others who have a record in their papers of an "immune" reaction—sometimes recorded as a "successful" vaccination (see, e.g., Cottrell and Knight, 1939, Illingworth and Oliver, 1944, Boeck, 1946; Marsden, 1946). [In fact, entries, as in pay books, that vaccination was performed on such and such a day are no indication at all that the person concerned is resistant to smallpox (see, e.g, Coleman, 1944; Black, 1945).]

The "immune" reaction is badly named—the term "immediate" is preferable—because this type of lesion may occur under the following conditions

1. It may be due to trauma only.
2. A similar lesion occurs in the early days of an accelerated reaction.
3. It may be due to weakly potent lymph.
4. It may be specific, but only due to sensitization to vaccinial protein acquired by a previous vaccination, and be equally well elicited by killed virus (see below).
5. It may be specific and indicate immunity to live virus, inoculation of killed virus giving a negative result.

Brom (1947) questions the value of the "immune" reaction, for persons susceptible to living vaccinia virus may react to heated virus in a manner closely simulating the immune reaction. Further, persons may be immune to live vaccinia as shown by failure to "take" on repeated revaccination, yet they do not show the reaction of immunity.

It is evident, therefore, that the reaction of immunity can be recognized with certainty only if there is a transient papule surrounded by an areola at the site of insertion, and there is no reaction with heated lymph.

The position is admirably summarized by Marsden (1946) who states "while it is probably true that an immediate reaction is the normal response to vaccination of the completely immune individual, the evidence that this reaction can occur in a subject who is susceptible to vaccinia or to smallpox appears to be overwhelming."

Significance of "Failure to Take"

It cannot be emphasized too strongly that the commonest cause for a failure to "take" on revaccination (or vaccination) is technical Either the lymph has become impotent from exposure to atmospheric temperature, or the scarification has been too superficial, or the antiseptic used to cleanse the arm has not dried, and has inactivated the virus.

When a revaccination does not "take," the person must be revaccinated on 2 or 3 occasions on different areas of skin. In practically every case some type of positive reaction will occur This has been emphasized by recent workers (D'Arcy, Moore, and Whetter, 1943, Marsden, 1946, Mole, 1947). Now and again one meets with the person who, though carefully observed, fails to show any response It is best to issue these persons with a certificate of "insusceptibility to vaccinia" Some of these persons may be immune to variola, but it is most unwise to regard this as established. There is a well known example in the literature of a soldier vaccinated 10 times in one year, failing to "take" on each occasion, yet dying of smallpox (Easton, 1945) Other workers have described cases of smallpox shortly after a "failure to take" (see, e g , Beaumont, 1946)

ALLERGY IN REVACCINATION

Persons who have been previously vaccinated may develop a sensitivity to reinoculation of virus, and this can be demonstrated with heated antigen (von Pirquet, 1907, 1911, Hooker, 1925, 1929, Leake, 1936) It can also be elicited with killed and washed suspensions of EB's (Craigie and Wishart, 1933) The reaction comes on within 3 days, and is identical in appearance with the immediate reaction No such reaction occurs in persons being vaccinated for the first time De-

vaccinial vesicle may induce an immunity to smallpox lasting for several years, usually about 10, the duration is very variable, and in certain cases may be quite short, about 2 years. It is probable that immunity can be broken down by an overwhelming dose of the infecting agent. Stevenson (1944) quotes a number of published cases of smallpox occurring at short intervals after successful vaccination, *even under one year. Modern practice is to advise "little and often" as the guiding* rule for persons likely to be heavily exposed, such as health and port officers, medical men, and nurses, and to revaccinate every 6–12 months. We may regard 4–5 years as the average duration of resistance, but this may often extend to a longer interval.

Smallpox in the vaccinated. The person who has acquired resistance to smallpox by vaccination usually suffers from a modified type of illness, ranging from the mild "contact fever" of the highly immune to the atypical case with rash. This question is fully discussed on page 294. It must be emphasized that the protective power of vaccination "wears off" in a definite order, and that protection against the early toxemic phase is lost before the rash-inhibiting property. This characteristic points to the wisdom of frequent revaccination of highly exposed persons.

Influence of number of insertions on protection. There has been much discussion regarding whether greater protection is afforded by several insertions than a single one. The Committee on Vaccination (1928) concluded that the greater the number of vaccinial scars, the more the protection against death from smallpox Thus from 1901–1904 the mortality among those showing 4 or more scars was 5.44 per cent, but 17.94 per cent. in those with only a single scar. The death rate was lowest (6.95 per cent.) in those who had a minimum vaccinated area of half a square inch, and highest (16.93 per cent.) in those where the area was less than one-third of a square inch They concluded that the number of inoculations had more significance in regard to protection against death than the combined areas of the scars. Lehmann (1936*a*), on the contrary, criticized these conclusions.

Stevenson (1944) points out that apparent failures to protect have followed vaccination by one as well as multiple insertions. It is widely accepted, nevertheless, that multiple insertions do confer greater protection

Marsden (1946) concludes that the state of our knowledge regarding the protective value of single mark vaccination remains where it was—there is yet no conclusive evidence. He points out, however, that recent practice has been to recom*mend 3 insertions in the face of an epidemic. Certainly this practice is to be* commended.

Influence of potency of lymph. Although it has been suggested that the potency of the lymph determines the degree and duration of protection, Stevenson (1944)

per cent. or 100 per cent. "takes" in a large number of people.

Immunity in the "Herd"

It is the general experience that vaccination of disciplined bodies such as troops lowers very markedly the incidence of smallpox when the men come into contact with the disease, e g, in the civilian population Oft-quoted evidence is that of the Prussian Army in the Franco-Prussian War (see Stevenson, 1944) However, it is recognized that even in such bodies of troops, smallpox will occur, and complete freedom cannot be expected, especially if the disease is prevalent in the civilian population

There is evidence that vaccination of civilians in endemic areas also tends to lessen the general incidence of the disease. A few examples may be quoted For example, owing to the geographical position of Palestine, the disease was at one

INTERNATIONAL CERTIFICATE OF VACCINATION AGAINST SMALLPOX

THIS IS TO CERTIFY THAT . . . .

(Age . . .. Sex . .) whose signature appears below has this day been vaccinated by me against smallpox.

Origin and Batch No. of vaccine ....

Official Stamp	Signature of Vaccinator . ...
	Official Position .. . .
	Place .... Date ....

Signature of person vaccinated . . ..

Home Address ....

Important Note: In the case of primary vaccination the person vaccinated should be warned to report to a medical practitioner between the 8th and 14th day, in order that the result of the vaccination may be recorded on this certificate. In the case of revaccination the person should report within 48 hours for first inspection in order that any immune reaction which has developed may be recorded.

THIS IS TO CERTIFY THAT the above vaccination was inspected by me on the date(s) and with the result(s) shown hereunder:

Date of Inspection	*Result*
....	....
....	....
....	....

Official Stamp	Signature of Doctor . ...
	Official Position . ...
	Place .... Date ....

Use one or other of the following terms in stating the result, viz: "Reaction of immunity," "Accelerated reaction (vaccinoid)," "Typical primary vaccinia." A certificate of "No reaction" will not be accepted.

Signature of person vaccinated ....

(This certificate is not valid for more than 3 *years from date of issue).*

FIG 30 International certificate of vaccination against smallpox

don (1936) where from 1928–1934, 14,000 patients were treated in the London smallpox hospitals without a single case of the disease among the staff protected by vaccination

Time of onset It is generally agreed that by the time the vaccinial vesicle has formed, the vaccinated person is resistant to smallpox Vaccination after exposure to smallpox cannot be relied upon to prevent the disease, although it may modify it (see, e g, Macgregor, 1942, Clark, 1944), especially is vaccination likely to fail to protect if the vaccinial lesion takes longer to mature than usual (see Marsden, 1946)

Duration Although there is every reason to believe that the development of a

vaccinial vesicle may induce an immunity to smallpox lasting for several years, usually about 10, the duration is very variable, and in certain cases may be quite short, about 2 years It is probable that immunity can be broken down by an overwhelming dose of the infecting agent. Stevenson (1944) quotes a number of published cases of smallpox occurring at short intervals after successful vaccination, even under one year. Modern practice is to advise "little and often" as the guiding rule for persons likely to be heavily exposed, such as health and port officers, medical men, and nurses, and to revaccinate every 6–12 months We may regard 4–5 years as the average duration of resistance, but this may often extend to a longer interval.

Smallpox in the vaccinated. The person who has acquired resistance to smallpox by vaccination usually suffers from a modified type of illness, ranging from the mild "contact fever" of the highly immune to the atypical case with rash. This question is fully discussed on page 294 It must be emphasized that the protective power of vaccination "wears off" in a definite order, and that protection against the early toxemic phase is lost before the rash-inhibiting property This characteristic points to the wisdom of frequent revaccination of highly exposed persons

Influence of number of insertions on protection There has been much discussion regarding whether greater protection is afforded by several insertions than a single one. The Committee on Vaccination (1928) concluded that the greater the number of vaccinial scars, the more the protection against death from smallpox Thus from 1901–1904 the mortality among those showing 4 or more scars was 5 44 per cent., but 17 94 per cent in those with only a single scar The death rate was lowest (6 95 per cent.) in those who had a minimum vaccinated area of half a square inch, and highest (16 93 per cent.) in those where the area was less than one-third of a square inch They concluded that the number of inoculations had more significance in regard to protection against death than the combined areas of the scars Lehmann (1936a), on the contrary, criticized these conclusions

Stevenson (1944) points out that apparent failures to protect have followed vaccination by one as well as multiple insertions. It is widely accepted, nevertheless, that multiple insertions do confer greater protection

Marsden (1946) concludes that the state of our knowledge regarding the protective value of single mark vaccination remains where it was—there is yet no conclusive evidence. He points out, however, that recent practice has been to recommend 3 insertions in the face of an epidemic. Certainly this practice is to be commended.

Influence of potency of lymph Although it has been suggested that the potency of the lymph determines the degree and duration of protection, Stevenson (1944) questioned whether the antigenicity of a lymph depends on potency, provided the latter is sufficient to insure a "take" That the lymph "takes" and produces a vesicle is all that matters for the individual He knows of no evidence that the protection in an individual vaccinated successfully is affected by whether the lymph gives 90 per cent or 100 per cent "takes" in a large number of people

Immunity in the "Herd"

It is the general experience that vaccination of disciplined bodies such as troops lowers very markedly the incidence of smallpox when the men come into contact with the disease, e g, in the civilian population Oft-quoted evidence is that of the Prussian Army in the Franco-Prussian War (see Stevenson, 1944) However, it is recognized that even in such bodies of troops, smallpox will occur, and complete freedom cannot be expected, especially if the disease is prevalent in the civilian population

There is evidence that vaccination of civilians in endemic areas also tends to lessen the general incidence of the disease. A few examples may be quoted For example, owing to the geographical position of Palestine, the disease was at one

time a serious problem, but by thorough vaccination control has been achieved (Balfour and Scott, 1924; Masterman, 1925; Stuart and Krikorian, 1930). In China, similar observations have been made (Uttley, 1938), and in Sweden (Halldén, 1937), and elsewhere (League of Nations, 1933). In India, Rogers (1945) notes the steady decline in the total smallpox deaths, and in average rates, coincident with a rise in the average numbers of vaccinations. At the period of the most rapid decline in smallpox incidence in British-administered territory, the death rates in states with little vaccination were up to 37 times as great as in neighboring fairly well-protected British-administered areas.

Useful evidence for the effect of vaccination in lowering the general incidence of smallpox comes from various American workers, many of whom draw attention to the different laws of the various states (e.g., Woodward, 1930, 1932, 1933, Feemster *et al*, 1932; Woodward and Feemster, 1933; Collins, 1936; Hedrich, 1936, Dauer, 1940, Hampton, 1943). The general experience is that where laws requiring vaccination for school attendance have been in force, smallpox has practically disappeared (Dauer). Hampton gives these figures: In states where vaccination is *essential for school attendance, the annual case rate of smallpox per 100,000* is 0.8, but in states where there are no definite regulations of value, the incidence is 11.1. In Canada important evidence comes from Groulx of Montreal (1940) who claims to have eradicated smallpox by measures directed to maintaining the number of vaccinated persons at the highest possible level.

More evidence comes from the results of mass vaccination in European cities. In recent experience, such campaigns were carried out in the Glasgow and Edinburgh outbreaks of 1942, when it appeared that the epidemic was "getting out of hand." The subsequent control of the epidemic appeared to be due to the raising of herd immunity following the introduction of mass vaccination. Not all, however, believe that the raising of herd resistance by this means is the cause of the cessation of the epidemic; they suggest that the epidemic is already virtually completed at the time of introduction of mass vaccination (see in particular, Millard, 1943 *a*, *b*, 1945 *a*, *b*).

IMMUNITY TO VACCINIA AFTER SMALLPOX

Immunity to vaccinia becomes complete a few days after the appearance of the focal rash, when vaccination no longer "takes." For example, in the London alastrim outbreak Marsden (1936) found that 34 per cent of 377 patients vaccinated on the first day of the focal rash developed a successful vaccination, but no vaccination was successful after the 6th day of the outcrop.

Although second attacks of smallpox are unusual, it is not infrequently possible to vaccinate successfully a person who has suffered from smallpox in the past (see, e.g., Dearing and Rosenau, 1934).

DISTRIBUTION OF VIRUS IN THE VACCINATED SUBJECT

Although the majority of vaccinated persons does not show any obvious signs or symptoms of generalized vaccinial infection, there is good reason to suspect that the virus is capable of entering the blood stream and causing a transient and generalized invasion of various organs. Thus, Herzberg-Kremmer and Herzberg (1930–1) found the virus in the blood in certain normal cases of vaccination between the 3rd and 10th days after inoculation. Virus was usually absent from the cerebrospinal fluid and the pharynx, but in certain cases, where the response to inoculation was excessive, it could be recovered from the cerebrospinal fluid, blood, and pharynx. The virus has been isolated from the tonsil (Gins *et al*, 1929) and nasal passages (*Goschanskaja et al*, 1932). Walthard (1926) states that he failed to isolate vaccinia virus from the cerebrospinal fluid of 12 patients 12 days after vaccination. Eckstein (1930) found no evidence of increased meningeal permeability, using the bromine test.

VACCINATION AND PREGNANCY

There is no evidence to suggest that vaccination during pregnancy interrupts the normal course of events. Furthermore, attention has been drawn to the fact that even if the fetus becomes infected, miscarriage does not always occur, and Lynch (1932) has quoted 47 cases in which children were born alive with pustular lesions on their skin (see also Marsden and Greenfield, 1934)

COMPLICATIONS OTHER THAN ENCEPHALITIS

Very rarely vaccination, and even less commonly revaccination, is followed by a complication

Nonspecific Vaccinial Rashes

A nonspecific rash may develop 6–14 days after vaccination. In most cases the rash is of the erythema multiforme type, morbilliform, or urticarial A causal factor may be the absorption of small traces of foreign serum from the lymph, or of toxic substances from the pustules Various workers have described rashes of this type (Rolleston, 1925, Chalke, 1931, 1941, Akiyama, 1937, McKenzie, 1943, Clark, 1944, Director, 1944) Bloch (1942) reported over 100 postvaccinial rashes out of half a million vaccinations performed in Glasgow in 1942 Most of these developed 7–11 days after primary vaccination in children but the limits were 2–49 days afterwards, most were erythemas, some were papular urticaria, and some were erythema multiforme.

Generalized Vaccinia

In a small proportion of cases, a generalized vaccinial eruption (from which the virus can be isolated) develops 6–14 days after vaccination (Drago, 1924; Gins, 1930*b*, de Vere Shortt, 1933, Dible and Gleave, 1934, Chaudhuri, 1935, Ellis, 1935, Ohta, 1935, Evans, 1937, Rolleston, 1937, Wollnitza, 1938, Eldahl, 1939, Regamey, 1940, Barber, 1942, Coombes and Behrman, 1943, Jubb, 1943, Clark, 1944, Director, 1944, Finn, 1944, Wollenman, 1944, Gropper, Lamanna, and Stewart, 1945; Belam, 1946).

In some cases of this sort, infection is probably transferred by auto-inoculation, with the fingers In true generalized vaccinia, the virus normally present in the blood of vaccinated persons localizes in the skin, the syndrome being analogous to generalized vaccinia in the rabbit Lesions of the skin may predispose to the localization of the virus It has been suggested that there is an association between allergy and postvaccinial manifestations (Davidson and Davis, 1943)

The serum of a recently vaccinated person has been used with success in treatment (Chesney and Jubb, 1944)

Accidental (Heterogenous) Vaccinia

Persons not themselves bearing a vaccinial lesion may be accidentally infected by contact with a case of vaccinia, and develop lesions on the skin 6–10 days later, the source of infection may be soiled bandages, towels, or bath water (de Vere Shortt, 1933, Clark, 1944).

Children suffering from eczematous skin eruptions are prone to develop vaccinial eruptions if they come in contact with a vaccinated person (Graves and Dowman, 1937, Albrigo, 1938, Snoek, 1938, Schmid, 1940, Brown, 1944, Petersilge and Toomey, 1944, Hershey and Smith, 1945) Burns are also liable to become infected with vaccinia (Nimpfer, 1936) The term eczema vaccinatum or heterogenous vaccinia may be applied to this condition Accidental infection of the nose has been reported (Ayo and Braley, 1942)

Postvaccinial Tetanus

This may be due to contamination of lymph with tetanus bacilli, but more commonly the infection is introduced by dirty earth-soiled fingers or dressings (see *Colò*, *1932*, Recchia, 1939, *Ambrosioni*, *1940*). *Felt* toe pads have given rise to tetanus after use as dressings for vaccination sites (Armstrong, 1925, *1929 b*, McVail, 1925).

Vaccinial Infections of the Eyes

The conjunctivae can become infected by auto-inoculation (Folk and Taube, 1933, Sezer, 1938, Atkinson and Scullard, 1940; Laval, 1940, Berkley, 1942, Klumzinger, 1944; Brav, 1945). The condition of keratitis postvaccinolosa is described (Sinaiko, 1931), also vaccinial diskiform keratitis (Perera, 1940).

Rarer Complications

The formation of *keloids* in the vaccination scar has rarely been reported (Louste and Rabut, 1932). *Glomerulonephritis* has been observed following revaccination (Herbut, 1944). Vaccination may cause an exacerbation in a latent tuberculous focus (Keers and Steen, 1943).

Vaccine lymph has been found contaminated with the virus of foot-and-mouth disease (Magnusson, 1930, van Heelsbergen, 1931), but there is no evidence that this is more than an extreme rarity (Gildemeister, 1931, Gildemeister and Helm, 1931–2).

THE SAFETY OF VACCINATION

It cannot be emphasized too strongly that all the complications mentioned above are so exceedingly rare in occurrence that they should never be regarded as arguments to be used against vaccination, since the safety of the procedure is absolutely unquestionable; Rhodes (1930), for example, mentions that he vaccinated 16,000 persons within a period of 4 months at the time of an epidemic, without a single case of ill effects being reported Likewise, Donnally and Nicholson (1934) successfully vaccinated 500 newborn infants against smallpox, and found the procedure to be perfectly safe, for it neither retarded the growth nor affected the nutrition of the child, and was usually unaccompanied by fever.

Statistical data indicating the total number of primary vaccinations and deaths from vaccinia at all ages and under one year old, in England and Wales from 1875 to 1925, have been summarized in the *Report of the Committee on Vaccination* (1928) These figures further emphasize the comparative rarity with which complications are encountered during the course of vaccination and reveal that in the period 1886 to 1891, during which 4,290,000 infants were vaccinated, there were 279 deaths at all ages, whereas in the years 1911 to 1925 when 5,500,000 were inoculated there were only 128 deaths at all ages

It has been said that severe vaccination reactions are commoner in the stout, and in women (Buchanan and Laidlaw, 1942).

THE WASSERMANN REACTION IN VACCINATION

Vaccination is one of the conditions that gives rise to a biological false positive WR (see, e g, Lynch, Boynton, and Kimball, 1941, Thomas and Garrity, 1941, Favorite, 1943, 1944, Rein and Elsberg, 1945).

CHAPTER XXXV

POSTVACCINAL[1] ENCEPHALITIS

FOR some years very considerable interest has been taken in an occasional sequel of the usually harmless procedure of vaccination. Such cases of postvaccinal encephalitis were probably first observed in 1905 and 1906 by Comby in France (see 1926), and later, in 1912 by Turnbull in London (see Turnbull and McIntosh, 1926). It was not, however, until 1922–3 that the disease assumed serious proportions. At this time, a number of children were stricken with a grave, often fatal, nervous illness some 10 or more days after a routine, apparently otherwise normal, vaccination.

Holland was particularly visited, and the complication had a considerably higher incidence there than in other countries Numerous cases occurred in Britain, and formed the subject of many papers and official reports Soon it came to be realized that the incidence of this condition was more widespread than at first supposed, [illegible] United States [illegible] It is related, [illegible] vaccination, and other conditions

With regard to literature, in Britain the disease was first reported officially by the Andrewes Committee, which met in 1925, and next by the Rolleston Committee, which was appointed on February 4, 1926. The findings of these committees were published in an official report in 1928 (*Report*, 1928). The Rolleston Committee published a further report in 1930 (*Report*, 1930). These reports are most comprehensive, and should be studied by all interested Certain other reports and reviews should also be read (Levaditi, Nicolau, and Sanchis-Bayarri, 1927, *League of Nations Report*, 1928, Armstrong, [illegible] Flexner, 1929 *a*, *b*, Matheson Committee, [illegible] ge, 1931, see also, 1932, Thomp- [illegible] Bogaert, 1937, Sindbjerg-Hansen, [illegible] some in the British outbreaks of [illegible]

CLINICAL FEATURES

Incubation period. The commonest incubation period is from 10 to 13 days, the day of maximum incidence being the 12th. Cases have developed, however, within the limits of 2 to 26 days after vaccination.

Onset and course The child is usually taken ill suddenly, the symptoms are obviously cerebral, such as headache, squints, and vomiting The temperature is raised, and the intellect dulled Drowsiness is present and increases to unconsciousness in some days Paralyses, usually of the spastic type, may occur In certain cases the picture is more meningitic, with neck rigidity, eye changes, convulsions, and other evidences of meningeal irritation Kernig's sign may be elicited, and also the *tâche cérébrale* The vaccination lesions usually look quite normal, although on rare occasions they have appeared unduly severe.

Although the British cases described in the *Reports* of 1928 and 1930 were more or less uniform in symptomatology, elsewhere more varied manifestations were noted Lucksch (1926), for example, described cases as falling into the following types cortical parenchymatous, resembling encephalitis lethargica, meningitic, and

[1] The term "postvaccinal" is the one most commonly used, and we here follow this practice Elsewhere in the book, however, we use "vaccinial" as the adjective derived from "vaccinia"

Postvaccinial Tetanus

This may be due to contamination of lymph with tetanus bacilli; but more commonly the infection is introduced by dirty earth-soiled fingers or dressings (see Colò, 1932, Recchia, 1939; Ambrosioni, 1940) Felt toe pads have given rise to tetanus after use as dressings for vaccination sites (Armstrong, 1925, 1929 *b*, McVail, 1925).

Vaccinial Infections of the Eyes

The conjunctivae can become infected by auto-inoculation (Folk and Taube, 1933; Sezer, 1938; Atkinson and Scullard, 1940; Laval, 1940, Berkley, 1942; Klumzinger, 1944; Bray, 1945). The condition of keratitis postvaccinolosa is described (Sinaiko, 1931), also vaccinial diskiform keratitis (Perera, 1940).

Rarer Complications

The formation of *keloids* in the vaccination scar has rarely been reported (Louste and Rabut, 1932). *Glomerulonephritis* has been observed following revaccination (Herbut, 1944). Vaccination may cause an exacerbation in a latent tuberculous focus (Keers and Steen, 1943).

Vaccine lymph has been found contaminated with the virus of foot-and-mouth disease (Magnusson, 1930; van Heelsbergen, 1931), but there is no evidence that this is more than an extreme rarity (Gildemeister, 1931, Gildemeister and Helm, 1931–2).

THE SAFETY OF VACCINATION

It cannot be emphasized too strongly that all the complications mentioned above are so exceedingly rare in occurrence that they should never be regarded as arguments to be used against vaccination, since the safety of the procedure is absolutely unquestionable, Rhodes (1930), for example, mentions that he vaccinated 16,000 persons within a period of 4 months at the time of an epidemic, without a single case of ill effects being reported. Likewise, Donnally and Nicholson (1934) successfully vaccinated 500 newborn infants against smallpox, and found the procedure to be perfectly safe, for it neither retarded the growth nor affected the nutrition of the child, and was usually unaccompanied by fever.

Statistical data indicating the total number of primary vaccinations and deaths from vaccinia at all ages and under one year old, in England and Wales from 1875 to 1925, have been summarized in the *Report of the Committee on Vaccination* (1928) These figures further emphasize the comparative rarity with which complications are encountered during the course of vaccination and reveal that in the period 1886 to 1891, during which 4,290,000 infants were vaccinated, there were 279 deaths at all ages, whereas in the years 1911 to 1925 when 5,500,000 were inoculated there were only 128 deaths at all ages.

It has been said that severe vaccination reactions are commoner in the stout, and in women (Buchanan and Laidlaw, 1942).

THE WASSERMANN REACTION IN VACCINATION

Vaccination is one of the conditions that gives rise to a biological false positive WR (see, e g, Lynch, Boynton, and Kimball, 1941, Thomas and Garrity, 1941, Favorite, 1943, 1944, Rein and Elsberg, 1945).

tion (see McIntosh, 1928, McIntosh and Scarff, 1927–8, Perdrau, 1928, Turnbull, 1928). Demyelination occurs in the form of wide "sleeves" around vessels, chiefly veins These areas sometimes fuse, to form large plaques Although Perdrau pointed out that the demyelinated area had no relation to the actual distribution of the vessel, it is now believed by some that vascular lesions play a predominant rôle in the causation of the demyelinating diseases

Globus (1932) drew attention to a source of error in examining small areas of supposed demyelination. He found that if such areas were closely examined, the myelinated fibers were often seen to be intact, but pushed away from the vessel by infiltrating cells, thus giving a false appearance of demyelination

2. *Perivascular infiltration.* There are usually a few cells infiltrating the adventitial sheath, perhaps one or two rows, where this infiltration is slight, the commonest cells are plasmacytoids More characteristic, however, is the occurrence of an extra-adventitial infiltration, composed of microglial cells and some polymorphs, hypertrophied neuroglia may also be found in these lesions, diffusely, or in a ring at the periphery (Perdrau).

3 *Diffuse infiltration* In cases where the extra-adventitial infiltration is very marked, there may be a more widespread increase of cells throughout the parenchyma

4 *Vascular changes* Hyaline thrombi may be found occasionally in cases of postvaccinal encephalitis Putnam (1937) has recorded the presence of more definitely organized thrombi Small perivascular hemorrhages may occur, but are unusual. Swelling and proliferation of the vascular endothelial lining is also a feature.

5 *Nerve cells* The most characteristic feature is that the cells are usually well

post-

it this

6. *Subacute lesions* Subacute cases have been reported where scarring was present, there was also an intense cellular infiltration, and fat-granule cells were present in large numbers in the vessel sheaths (Turnbull and McIntosh, 1926, Perdrau, 1928, Turnbull, 1928).

Distribution of lesions Inflammatory lesions occur particularly in the cerebral cortex, midbrain (especially substantia nigra), basal portion of the pons, and in the upper part of the medulla In the cerebrum and cerebellum the white matter is more involved than the gray (Perdrau).

As regards the cord, the infiltration is maximal in the lumbar region, the white matter, especially in the lateral and anterolateral columns, shows widespread demyelination

Changes in Other Parts of the Body

Perdrau (1928) recorded a mild lymphocytic infiltration of the posterior root ganglia in one case, no lesions were found in the brachial plexus or intervertebral ganglia of the affected side of the body by Coyle and Hurst (1929), thus rendering it unlikely that virus had spread to the central nervous system by nerve pathways

Turnbull and McIntosh (1926) found that the pathological features of the vaccination scabs, in cases of postvaccinal encephalitis, were absolutely normal (see p 384), neither did they find any lesions in the regional glands, apart from the nonpurulent infiltration present in normal vaccinated persons

In Russell and Oddie's (1928) case there was congestion of the kidneys Microscopically, the glomeruli were swollen, the nuclei were increased in numbers, the epithelium of the tubules showed cloudy swelling, and there was a deposit of calcium salts.

poliomyelitic, with chief incidence in the cord. Glanzmann (1927) mentioned the following varieties:

1. Meningeal symptoms predominated in this type
2. Encephalitic symptoms occurred with paralyses.
3. *Encephalitis was associated with tetanic spasms (see also Mader, 1929, Hassin* and Geiger, 1930).
4. Encephalitic symptoms of somnolence and cranial nerve palsies were present
5. The Dutch type of encephalitis was often fatal, with somnolence and convulsions, but no paralyses or spasms
6. The manifestations were those of disseminated encephalomyelitis with meningeal symptoms

Kaiser and Zappert (1938) have described bulbar cases. Peake (1929) and Magé (1937) have recorded cases of transverse myelitis (see also Brockbank, 1931, Style and Fleming, 1943; McKenzie, 1943, Dixon, 1944). Jermulowicz (1930) described 2 cases that resembled poliomyelitis (see also Perritt and Carrell, 1930).

Sequelae (which are uncommon) usually take the form of epilepsy and mental changes (see *Report*, 1928, Armstrong, 1932; Kaiser and Zappert, 1937).

CLINICAL PATHOLOGY

The cell count in the cerebrospinal fluid may be increased up to 100 to 150 mononuclear leukocytes per c mm; protein may also be increased (see *Report, 1928, Roper, 1933, Kaiser and Zappert, 1938). The white cells of the blood may* be increased, to 10,000 or even 18,000 per c.mm.

It is as well to carry out blood culture in all suspected cases, as it has been shown that septicemia may closely simulate postvaccinal encephalitis (Grey and Whittaker, 1930, Priest, 1930)

MORTALITY

The mortality figures have, of course, varied from time to time. The case mortality rate of the cases described in the *Report* of 1928 was 58 per cent., the mortality in 71 American cases reported by Armstrong (1932) was 37 per cent. Probably an average case mortality rate is about 40 per cent, showing that the disease is a very serious one

PATHOLOGY

The pathology of postvaccinal encephalitis is of great interest, mainly because it shows the disease to be closely related to numerous other conditions characterized by demyelination In Britain the papers attracting main atttention have been those of Turnbull and McIntosh (1926), Perdrau (1928), and Turnbull (1928), and it is on these that the following account is mainly based Numerous other authors have described the pathological features of the condition (Bastiaanse *et al*, 1925, Bouman and Bok, 1927, Lucksch, 1927, Pondman, 1927, McIntosh and Scarff, 1927–8, Bijl, 1928, McIntosh, 1928, [illegible] 1928,
Coyle and Hurst, 1929, Kling, Lon [illegible] erido,
1930, Bastiaanse, 1931, von Herre[illegible] arren,
1931, Globus, 1932, Spielmeyer, 1932, Kokken, 1937, Kaiser and Zappert, 1938, Lamm, 1938, Swan, 1944)

Central Nervous System

Naked-eye, the meninges appear congested Microscopically, there is a mild inflammatory reaction with some hemorrhages, the infiltrating cells are mainly lymphocy[illegible] cells
1. [illegible] striking and characteristic lesion of postvaccin[illegible] er, Turnbull and McIntosh (1926) clearly descri[illegible] ere soon realized to be areas of demyelina-

tion (see McIntosh, 1928, McIntosh and Scarff, 1927–8, Perdrau, 1928, Turnbull, 1928). Demyelination occurs in the form of wide "sleeves" around vessels, chiefly veins These areas sometimes fuse, to form large plaques Although Perdrau pointed out that the demyelinated area had no relation to the actual distribution of the vessel, it is now believed by some that vascular lesions play a predominant rôle in the causation of the demyelinating diseases.

Globus (1932) drew attention to a source of error in examining small areas of supposed demyelination. He found that if such areas were closely examined, the myelinated fibers were often seen to be intact, but pushed away from the vessel by infiltrating cells, thus giving a false appearance of demyelination.

2. *Perivascular infiltration* There are usually a few cells infiltrating the adventitial sheath, perhaps one or two rows, where this infiltration is slight, the commonest cells are plasmacytoids More characteristic, however, is the occurrence of an extra-adventitial infiltration, composed of microglial cells and some polymorphs, hypertrophied neuroglia may also be found in these lesions, diffusely, or in a ring at the periphery (Perdrau).

3 *Diffuse infiltration* In cases where the extra-adventitial infiltration is very marked, there may be a more widespread increase of cells throughout the parenchyma

4 *Vascular changes* Hyaline thrombi may be found occasionally in cases of postvaccinal encephalitis. Putnam (1937) has recorded the presence of more definitely organized thrombi Small perivascular hemorrhages may occur, but are unusual Swelling and proliferation of the vascular endothelial lining is also a feature

5. *Nerve cells* The most characteristic feature is that the cells are usually well preserved, even in areas showing a profuse cellular infiltration

An encephalitozoon-like parasitic cyst was described in the nerve cells of postvaccinal encephalitis cases by Kling, Wassén, and Faahraeus (1932 *a*, *b*), but this observation has not been generally confirmed

6 *Subacute lesions* Subacute cases have been reported where scarring was present, there was also an intense cellular infiltration, and fat-granule cells were present in large numbers in the vessel sheaths (Turnbull and McIntosh, 1926, Perdrau, 1928, Turnbull, 1928).

Distribution of lesions Inflammatory lesions occur particularly in the cerebral cortex, midbrain (especially substantia nigra), basal portion of the pons, and in the upper part of the medulla In the cerebrum and cerebellum the white matter is more involved than the gray (Perdrau).

As regards the cord, the infiltration is maximal in the lumbar region, the white matter, especially in the lateral and anterolateral columns, shows widespread demyelination

Changes in Other Parts of the Body

Perdrau (1928) recorded a mild lymphocytic infiltration of the posterior root ganglia in one case, no lesions were found in the brachial plexus or intervertebral ganglia of the affected side of the body by Coyle and Hurst (1929), thus rendering it unlikely that virus had spread to the central nervous system by nerve pathways

Turnbull and McIntosh (1926) found that the pathological features of the vaccination scabs, in cases of postvaccinal encephalitis, were absolutely normal (see p 384), neither did they find any lesions in the regional glands, apart from the nonpurulent infiltration present in normal vaccinated persons

In Russell and Oddie's (1928) case there was congestion of the kidneys. Microscopically, the glomeruli were swollen, the nuclei were increased in numbers, the epithelium of the tubules showed cloudy swelling, and there was a deposit of calcium salts

EPIDEMIOLOGY

Incidence

One of the most characteristic features of postvaccinal encephalitis is the rarity with which it follows primary vaccination in infancy; the bulk of cases occur in children over 2 years of age. For example, in Holland from 1927 to 1936, Bastiaanse (1937) recorded only 9 cases in children below 2, although there were 116 in those aged 2 to 11. From 1923 to 1927 there was only 1 case of postvaccinal encephalitis in infants under 1 year, although 27,405 were vaccinated. He found that the ratio of cases of postvaccinal encephalitis to vaccinations was 1/2,900 from ages 2 to 11, but only 1/16,000 for those under 2.

In Holland, during the period of high incidence, the commonest age for children to be vaccinated was just before they went to school; accordingly, the majority of cases occurred in those aged 3 to 5. In England, however, if not vaccinated in infancy, the primary vaccination might be carried out at any time later, usually during the school period, the commonest age for postvaccinal encephalitis to develop, therefore, was from 6 to 14. In recent experience this age incidence has been confirmed (Anderson and McKenzie, 1942).

Sex. There seems often to have been a predominance of female cases Thus, in 62 cases cited in the English *Report* (1928) 40 were in females and 22 in males.

Grouping of cases. Certain small groups of cases have, on occasions, been noted e g in London, Bristol, Sheffield, and Wareham in Great Britain, in an American city (Armstrong, 1932); and in Kufstein in the Tyrol (Kaiser and Liedl, 1929) The bulk of cases have occurred sporadically, however, without any apparent connection between each other; familial cases are most unusual.

Geographical Distribution

At first recognized chiefly in Holland, Great Britain, and Germany, it is now known that postvaccinal encephalitis may occur in many other parts of the world. The disease appears to have been very common from 1922 to 1930, and to have become considerably less prevalent of recent years.

The following information on the geographical incidence of postvaccinal encephalitis has been gleaned from numerous original papers (*vide infra*), as well as from special reports (see in particular *League of Nations Report*, 1928; *Report*, 1928, 1929, 1930, *Bull Off int. Hyg publ.*, 1934, 1935, 1936, 1946)

Great Britain Turnbull investigated a case of postvaccinal encephalomyelitis in London in 1912. The results of this investigation were not generally known until, with McIntosh in 1926, he reported 6 further necropsies of similar cases. Three of these cases occurred in 1922, and 3 in 1923, Turnbull recorded a further case in 1928 Numbers of papers and reports have referred to the incidence of postvaccinal encephalitis in Britain (Winnicott and Gibbs, 1926, Martin, 1928, Perdrau, 1928, *Report*, 1928, 1930, 1931, Russell and Oddie, 1928, Taylor, 1929, Roper, 1933).

The official *Report* of 1928 gives the following information regarding the total numbers of cases brought to notice in England and Wales In November and December 1922 there were 11 cases, in the summer and autumn of 1923 there were 50 cases The cases of 1922 occurred in the London area Those in 1923 were widely dispersed over England and Wales, it was possible, however, to define a belt of incidence extending from Exeter and the Bristol Channel, via the Midlands, to Morpeth in Northumberland Cases occurred outside this belt in London and the Home Counties, it was noted that hardly any cases occurred on the coast In 1924 and 1925 there were only a few cases reported From January 1926 to October 1927 the disease became more prevalent, there being 25 cases, of these, 20 occurred in the first three-quarters of 1927, 11 of the 20 cases occurred in 2 groups, namely,

5 in Sheffield, all within 12 days, and 6 in a localized area on the Monmouth–Glamorgan boundary.

The later *Report* (1930) of the Rolleston Committee reported 80 cases occurring between 1 October 1927 and 30 September 1929. Two particular groupings were noted in this set of cases. First, during the last quarter of 1927, 7 cases occurred in Bristol and 2 in the neighboring district of Kingswood, further, 6 of the Bristol cases occurred in an area of 1 square mile. The second remarkable grouping was at Wareham village, where 5 cases of postvaccinal encephalitis occurred. Although there was some other evidence of grouping in various localities, 48 cases were widely scattered over the country.

recorded (*Bull Off. int. Hyg publ*, 1935), while from 1934 (October) to 1935 (October) only 1 case was recorded (*Bull Off. int. Hyg. publ*, 1936). In 1936 there were 5 cases (Morgan, 1938) A later case was that of Sakoschansky and Trenchard (1939).

Holland. Main interest has always centered in the Dutch cases, as the disease is commoner in Holland than elsewhere. Many papers and reports have been published by those who have investigated such cases (Bastiaanse *et al*, 1925; Bastiaanse, Bijl, and Terburgh, 1926, Terburgh, 1927, 1929, 1930, *League of Nations Report*, 1928, *Report*, 1928, Netter, 1929 *c*, Aldershoff, 1930 *a*, Jitta, 1930, 1931; Hekman, 1930, Paschen, 1930, Terburgh, 1930; Bastiaanse, 1931, 1932, 1937).

As regards the number of cases, Jitta (1931) reported that 186 occurred between 1924 and 1931. More recently, Bastiaanse (1937) referred to 125 cases between January 1, 1927 and January 1, 1936. In 1933 there were only 8 cases (*Bull Off. int Hyg. publ*, 1935), and in 1935 only 4 (*Bull. Off. int. Hyg publ*, 1936). It is evident, therefore, that the disease is much less common at the present day than it was from 1925 to 1930 A high incidence of postvaccinal encephalitis in small communities was a characteristic feature of the Dutch cases For example, in 2 large cities the incidence of postvaccinal encephalitis was 1 per 9,000 recently vaccinated persons, but in small towns the rate was 1 case per 63 vaccinations (*Report*, 1928).

The factors causing the high incidence of postvaccinal encephalitis must have been purely local, this was strongly suggested by the fact that a certain preparation of neurovaccine failed to produce any accidents in Spain, but when used for vaccination in Holland a number of cases was recorded (Paschen, 1930).

America. Various reports have referred to the incidence of postvaccinal en- ... Flexner 1929 *a*, *b*, Fulgham 1930, Tuthill, 1930; Wolf ... nd Warren, 1931; Roehm, ... 6, Lancaster, 1938). Bauer was able to find records of 74 cases up to 1935.

Germany. A number of cases has been recorded in Germany, and it would appear that at least 100 cases have now been described (Pette, 1927, Hamel, 1929, 1931, *Report*, 1929, Esser, 1930, Weichsel, 1931, Eckstein, 1929 *a*, *b*, 1932 *a*, *et al*, 1931, *Bull. Off int Hyg publ*, 1934, 1935, 1936 ...

With regard to *Austria*, Redlich (1927), K ... (1929) presented early reports Lately, Kaiser ... a monograph giving a bibliography of Austrian publications, they recorded 240 cases Stiefler (1938) has reviewed the cases occurring from 1930 to 1937.

Norway Holst (1935) refers to some 60 cases of the disease, one-third of which occurred in Oslo, although this town only contains one-tenth of the whole population (see also Holst, 1930, 1939, Ustvedt, 1930, *Bull. Off. int Hyg publ*, 1935). Voss (1938) refers to 80 cases between 1921 and 1937.

Sweden. A number of workers record the occurrence of postvaccinal encephalitis in this country (Kling, Lonberg, and Wassén, 1929; *Report*, 1929, Kling, 1932; Kling *et al.*, 1932 *a*; *Bull. Off. int. Hyg. publ.*, 1934, 1935, 1936, Olin, 1938).

In all the above countries the disease has been recognized quite commonly. In the countries listed below, only comparatively few cases have been recorded.

Australia Lockwood (1931) recorded a case that developed in 1925.

British Guiana. Grace (1929–30) reported a case.

Canada. Gordon (1931) referred to a probable case seen in 1914, and to a later one diagnosed histologically (see also Gordon and Rhea, 1932).

Czechoslovakia Lucksch (1924, 1925, 1926) drew attention to cases occurring in Bohemia from 1923.

Belgium. Probably under 20 cases have been recorded (see van Bogaert and Borremans, 1931; *Bull. Off. int. Hyg. publ*, 1935; Meunier, 1936–7, 1937, Van Den Branden and Nelis, 1936–7; Kokken, 1937).

France. Comby (1907, and see 1926) observed in 1905 and in 1906 what were perhaps the first 2 recognized cases of postvaccinal encephalitis The incidence of the condition has remained very low, comparatively few other papers having appeared (Dévé, 1929, Paisseau and Scherrer, 1929, Pagniez, 1930; Gounelle, 1931, Bertoye and Bouvier, 1932; Imbert, 1935; Giraud *et al.*, 1938, see also *Report*, 1929)

Italy. Taccone (1936) mentioned over 100 cases as having occurred in Italy, more recently Petragnani (1938) recorded 11 cases in 1936 and the first half of 1937.

Mexico Almazan (1936) recorded the occurrence of 8 cases since 1928.

Oceania Clouston and Quin (1937) referred to a case on the island of Nauru (0 15 S, 167 0 E.).

Roumania. Paulian, Arceesco, and Finkelstein (1932) recorded a case.

Russia. Syssine (1930) refers to the occurrence of postvaccinal encephalitis in this country

Switzerland Only a few cases have been reported from this country (see *Report*, 1929, Carrière, 1930, *Bull Off. int. Hyg. publ.*, 1936).

Yugoslavia. The occurrence of cases in this country has been referred to by Yoannovitch (1930)

India Cases have only rarely been recorded, a recent one being that of Nicol (1938) in the Punjab.

Africa. The complication is surprisingly rare in Africa, despite the very large number of vaccinations performed (Davies, 1947)

Relationship to Cases of Smallpox

There does not seem to be any relation between the number of cases of postvaccinal encephalitis and smallpox occurring in a given locality. For example, the *Report* of 1928 states that there were 3 cases of postvaccinal encephalitis in both Gloucestershire and Oxfordshire, yet the former county had 617 cases of smallpox, and the latter none, further, in Worcestershire, with only 1 case of smallpox, there were 7 of postvaccinal encephalitis.

THE RÔLE OF VACCINATION IN THE ETIOLOGY OF POST-VACCINAL ENCEPHALITIS

The Lymph

There has never been reason to blame any particular sample of lymph

It has been suggested that postvaccinal encephalitis only became prevalent after the introduction of vaccine lymph which had at one time in its history been passed through a rabbit (Coplans, King, and Simpson, 1929) However, this does not explain the fact that postvaccinal encephalitis is now comparatively uncommon, although rabbit-passed virus is still in use

Number of Insertions

The later *Report* (1930) of the Rolleston Committee recorded 42 cases primarily vaccinated in 4 insertions, 2 cases in 3 or 4, 13 cases in 3, 7 cases in 2; and only 2 cases that were vaccinated in a single insertion Similar observations were recorded in the first *Report* (1928). It seems evident, therefore, that multiple insertions are to be deprecated, and single to be commended The *Report* of 1928 did actually contain such recommendations.

The Rôle of Primary Vaccination

The great majority of cases occurs after primary vaccination, and not after revaccination For example, in the later *Report* (1930) of the Rolleston Committee, 83 out of 90 cases were in primarily vaccinated persons. In 71 cases in the United States of America only 2 occurred in revaccinated patients (Armstrong, 1932). In Germany Hamel (1929) reported postvaccinal encephalitis to follow 46 primary vaccinations, and only 5 revaccinations In the Edinburgh mass vaccination campaign (1942) 20/23 cases were in persons vaccinated for the first time (Clark, 1944). It has been said that postvaccinal encephalitis following revaccination develops after an incubation period of about 5 days, as compared with the usual 12 days (*Hekman, 1930*).

Effect of Incidence of Vaccination

It is logical to ask whether an increased incidence of vaccination brings in its train an increased number of cases of postvaccinal encephalitis. The figures of the 1928 *Report* gave no direct support for such a relationship Thus, in Gloucestershire 27,800 tubes of lymph were issued to public vaccinators, and 3 cases of postvaccinal encephalitis resulted *In Worcestershire there were 7 cases of* postvaccinal encephalitis (i e., over double the Gloucestershire figures), but only 16,639 tubes of lymph were issued. Further, Oxfordshire had as many cases of postvaccinal encephalitis as Gloucestershire (3), but only 4,100 tubes were issued, as against 27,800 in Gloucestershire.

In apparent contrast to these English figures, Terburgh (1929) in Holland cites the following evidence that there is a relationship between the number of cases of postvaccinal encephalitis and the incidence of vaccination 188,000 vaccinations in March yielded 46 cases of postvaccinal encephalitis, 99,000 vaccinations in April yielded 14 cases of postvaccinal encephalitis, 46,000 vaccinations in May yielded 2 cases.

The question of the connection between the incidence of vaccination and the occurrence of postvaccinal encephalitis must, therefore, remain unsettled. There is no doubt, however, that groups of cases are now seldom seen except associated with a mass vaccination campaign

Ratio of Cases of Postvaccinal Encephalitis to Vaccination

In England and Wales the ratio of cases of postvaccinal encephalitis to cases of vaccination was 1/49,000, whereas in Holland it was 1/4,000 (*Report*, 1928), this suggested the presence in Holland of some local factor very potent in the causation of postvaccinal encephalitis In recent experience the incidence in Edinburgh in 1942, for instance, was 1 20,000 (Clark, 1944), in Glasgow 1/70,000 (Anderson and McKenzie, 1942), and in Fife 1 7,000 (Fyfe and Fleming, 1943).

PREVENTION OF POSTVACCINAL ENCEPHALITIS

The Rolleston Committee (*Report*, 1928) recommended that a trial be made of vaccination in one insertion, with a minimum of injury, and without crosshatching. They recommended that persons should be vaccinated *in infancy, between 2 and* 6 months, revaccinated at 5 to 7 years of age, and again at 14 to 16 years The

great point is to avoid primary vaccination of children over the age of infancy; for it will be recalled that the disease is very rare in infants, occurring mainly in those of school age. They also recommended that public vaccinators should inspect their patients 7 to 10 days later, and also after 14 to 17 days

SPECIFIC THERAPY

Certain authors have reported beneficial results to follow the administration of serum of persons recently vaccinated (Horder, 1929, Hekman, 1929, 1930, Roper, 1933, see also Paschen, 1930; Netter, 1931; Davidson and Thomas, 1942; Dunn, 1943; Fyfe and Fleming, 1943; see also Loutit and McClean, 1945). Horder and Roper administered the serum intrathecally, and Hekman intravenously. Béclère (1931) recommended serum of a vaccinated calf.

ATTEMPTED ISOLATION OF THE ETIOLOGICAL AGENT OF POSTVACCINAL ENCEPHALITIS

Writing in the *Report* of 1928, McIntosh and Blaxall recorded the presence of vaccine virus in the brains of 3 cases. At first this virus was maintained by rabbit passage, but later it could be passed through calves (see also Turnbull and McIntosh, 1926). Aldershoff (1930 *b*) was also able to isolate vaccinia virus from the central nervous system of fatal cases.

Certain authors have recorded the presence of vaccinia virus in the cerebrospinal fluid of up to a third of cases of postvaccinal encephalitis, although absent from that of normal vaccinated persons (Gildemeister, 1929, Eckstein, Herzberg-Kremmer, and Herzberg, 1930 *a*; Herzberg-Kremmer and Herzberg, 1930, 1932).

Despite these positive results, Gordon (*Report*, 1928) was unable to find the virus in the central nervous system of 5 cases of postvaccinal encephalitis, nor did suspensions of such tissues immunize rabbits against vaccinia Others have also failed to isolate virus (Bastiaanse *et al.*, 1925; Bijl, 1926, 1927; Kraus, 1927, Esser, 1930) This failure has been attributed to a virucidal substance in the brain (Bijl and Frenkel, 1929). Another possible explanation is that the condition of "autosterilizable neuroinfections" of French authors occurs; that is to say, that the host reacts to the presence of vaccinia so efficiently that the virus is all destroyed, and none can be isolated from the brain.

In conclusion, vaccine virus is certainly the only one which has been isolated from cases of postvaccinal encephalitis, but this has not been accomplished with sufficient regularity to bear much weight Further, it is probable that vaccine virus normally enjoys a wide distribution throughout the tissues of the vaccinated person, so that the finding of vaccine virus in the brain or cerebrospinal fluid of cases of postvaccinal encephalitis loses most of its apparent significance.

THEORIES OF THE ETIOLOGY OF POSTVACCINAL ENCEPHALITIS

A large number of theories has been put forward to explain the etiology of postvaccinal encephalitis, certain established facts should be borne in mind when considering these. First, postvaccinal encephalitis follows vaccination at an interval of about 12 days Second, the virus of vaccinia has been isolated from the brains of cases on a few occasions, this loses much of its importance, however, in view of the fact that the virus is known to disseminate in the body of vaccinated persons who do not develop postvaccinal encephalitis Third, a disease, similar histologically, follows measles, antirabies treatment, and perhaps other conditions Fourth, the histological picture of certain other demyelinating diseases is very similar to that of postvaccinal encephalitis

The various theories that have been advanced will now be discussed *seriatim* Information on the etiology of other demyelinating processes should also be read, e g., neuroparalytic accidents after rabies (see Ch LXXIX), and measles encephalitis (see Ch. XX).

1 *Cerebral vaccinia* It is most natural to suppose that postvaccinal encephalitis may be due to an invasion of the cerebral tissue by the vaccine virus itself, the strain being endowed perhaps with special neurotropic tendencies In favor of this theory, the incubation period is constant at about 12 days—a period similar to that of smallpox. More important, however, is the fact that vaccinia is the only virus ever isolated from the central nervous system in postvaccinal encephalitis Further, it should be noted that similar cases may occur in the course of smallpox (see p 290). Another point in favor is the fact that benefit has been produced by the serum of recently vaccinated persons On the experimental side McIntosh supported the theory because of similarities which he detected between the lesions of postvaccinal encephalitis and those produced, experimentally, by injection of rabbits and monkeys with vaccinia Eckstein and also Clearkin obtained results which support this theory, for they found changes reminiscent of postvaccinal encephalitis in monkeys inoculated by various routes (see p 325). McIntosh appended a minority report to that of the Andrewes Committee (*Report*, 1928), in which he supported this theory (*see also 1930, McIntosh and Scarff, 1927–8*). The theory of cerebral vaccinia has been upheld by others (Netter, 1929 *b*, 1931; Eckstein, Herzberg-Kremmer, and Herzberg, 1930 *a*, *b*).

There are, however, certain objections to this theory.

(*a*) Vaccination has been carried out for generations, yet apparently this complication has only recently been recognized

(*b*) The presence of virus in the brain does not necessarily indicate that it is playing any pathogenic rôle, as it is known to disseminate widely in the bodies of normal vaccinated experimental animals and human beings

(*c*) Even so, many authors have quite failed to isolate vaccinia virus from the brain or cerebrospinal fluid of cases

(*d*) The histological picture of postvaccinal encephalitis is generally held to be quite unlike that produced by intracerebral injection of vaccinia in animals

(*e*) There has never been evidence adduced to incriminate any particular batch of vaccine lymph No special tendency to neurotropism has been found in the virus in specimens of lymph giving rise to postvaccinal encephalitis On one occasion neurovaccine was used for vaccination in Spain, without production of postvaccinal encephalitis, the same vaccine was brought to Holland, where the usual high incidence of postvaccinal encephalitis occurred (Paschen, 1930).

(*f*) Some authors have quite failed to produce encephalitis in experimental animals after inoculation of the skin, despite maneuvres designed to cause the virus to localize in the nervous tissue (see p 318).

(*g*) Conditions similar to postvaccinal encephalitis follow infection by other agents, e g., measles virus, and during antirabies treatment It is difficult, then, to claim any specificity for vaccinia virus.

2 *Activation theory* A theory which has been widely held is that vaccination serves to activate some other virus which is lying latent in the body. Two viruses, in particular, have been investigated with regard to the possibility of their being stimulated by vaccination. For example, Gordon, as well as Perdrau, has shown experimentally that there is no evidence that herpes virus can be stimulated by vaccinia to produce a condition resembling postvaccinal encephalitis. Hurst and Fairbrother (1931) found no evidence to suggest that poliomyelitis virus could be activated by vaccinia

As it has not proved possible to incriminate any known virus, recourse has been

1933–4, 1935). We do not, however, feel able to support this theory, as there is virtually no positive evidence in its favor.

3. *Theory of fortuity.* It has been suggested that postvaccinal encephalitis is none other than encephalitis lethargica or polioencephalitis. For example, Levaditi, Nicolau, and Sanchis-Bayarri (1927) suggested that postvaccinal encephalitis is caused by vaccinia "lighting-up" the causal agent of encephalitis lethargica. They considered that, clinically, certain cases of the 2 diseases are alike, histologically also there are similarities; and there is difficulty in isolating a causal agent in both conditions. There are certain serious objections to this theory:

(*a*) The constancy of the incubation period argues against the cases being fortuitous examples of another known nervous disease.

(*b*) [illegible] usually distinguishable,

(*c*) [illegible] itis, one would expect that the characteristic virus would be isolated. The histological examination can also distinguish between the 2.

(*d*) With regard to both, there has seldom been any definite coexistence of postvaccinal encephalitis and typical cases of either polioencephalitis or encephalitis lethargica. Studies of the relative incidences and mortalities of the 3 conditions have not disclosed any relationship that would suggest that postvaccinal encephalitis is caused by polioencephalitis or encephalitis lethargica.

4. *Other infective agents.* (*a*) It has been suggested that postvaccinal encephalitis is caused by a virus which finds its way into the site of vaccination at the time of operation, or later (see, e.g., Aldershoff, 1935). The virus must presumably, therefore, either be present on the patient's skin, or else in the lymph used as inoculum. There is absolutely no evidence that such a virus exists, and the theory is a most unlikely one. It should be noted that although lymph has been found contaminated with foot-and-mouth virus (Van Heelsbergen, 1931) there is not the slightest evidence that such an occurrence is anything but the greatest rarity. At any rate, it is unlikely that the virus of foot-and-mouth disease could cause such a condition as postvaccinal encephalitis.

(*b*) It has been suggested that the cause of postvaccinal encephalitis is a *Pasteurella* organism showing bipolar staining (Aldershoff and Pondman, 1928). They claim to have isolated this organism from the vaccine lymph used, and the nasal discharge, in 1 case.

In rabbits they claimed that the intracerebral inoculation of vaccinia activated a bipolar organism already present (probably in the nasal passages), so that it could be isolated from the brain. Pette (1928) showed experimentally that rabbits inoculated with vaccinia virus might succumb to a *Pasteurella* infection. The vaccination activated these organisms lying in the nasal passages.

(*c*) Aldershoff (1930 *a*) does not believe that postvaccinal encephalitis is caused by vaccinia, and has blamed a *Monilia* organism.

(*d*) Heerup (1936) postulated that a primary focus of infection in the tonsils gave rise to a state of toxemia, and that this was the essential factor in the etiology of postvaccinal encephalitis.

(*e*) In one case it appeared as if hereditary syphilis acted as the predisposing cause (Murano, 1937).

(*f*) Caminopetros *et al.* (1938) claim to have isolated a hitherto undescribed virus, by animal inoculation, from the cerebrospinal fluid of one case of postvaccinal encephalitis.

5. *Theory of allergy.* Glanzmann (1927) suggested that postvaccinal encephalitis may be due to a local anaphylactic reaction in the central nervous system, and this theory has been supported by others (Mikulowski, 1927, Euzière and Pagès, 1928, van Bogaert, 1932). Evidence of an allergic state was obtained in one case by

McClure (1930), whose patient developed urticaria shortly after vaccination, postvaccinal encephalitis following in 10 days' time.

Finley (1938) has recently strongly supported the allergic theory He quotes von Pirquet's (1907) description of the primary lesion of vaccination as follows The lesion is composed of 2 parts (*a*) the papule—regarded as nonspecific, and (*b*) the areola—a specific virus response appearing about the 4th day, this areola rapidly increases in size from the 8th day, and is maximal on the 11th to 12th von Pirquet held that the areola was the result of the interaction of antibodies and virus in the neighborhood of the papule Finley's main argument is based on the presumption that antigen-antibody interaction occurs in other parts of the body, as well as the skin lesion, at this time. In evidence he states that the temperature rises, further, the local and general vaccinial eruptions that may be noted occur at the acme of the primary lesion, he emphasizes the constancy of the incubation period of postvaccinal encephalitis, which is slightly shorter after revaccination. Finally, he recalls that the brain of experimental animals acquires a local immunity after vaccination, and that the brain of a case of postvaccinal encephalitis neutralized vaccinia virus (Bijl and Frenkel, 1929). All these facts, he suggests, indicate that an antigen-antibody reaction may occur elsewhere in the body, including the brain. Granted that such a reaction does occur in the brain, it would probably take the form of a vascular thrombosis, and this we know produces demyelination Here we may quote 2 reports of experimental work

First, Alexander and Campbell (1937) sensitized guinea-pigs by a single injection of horse serum intraperitoneally, later, the "shock-provoking" dose was given directly into the brain Anaphylactic lesions were produced in the brain, having the following characteristics there were vascular thromboses and hemorrhages, necroses, demineralization, infiltration with leukocytes, microglia, oligodendroglia and astrocytes, the areas immediately peripheral to these lesions were anemic. They found similar, but very much smaller, lesions in unsensitized animals given a single intracerebral dose

Secondly, Abell and Schenck (1938) have employed the transparent chamber technique, whereby the living vessels in the rabbit's ear may be examined They first sensitized rabbits to horse serum, and later injected antigen intravenously, or into the transparent chamber. The second injection might be followed by a contraction of the arterioles, obliteration of the lumina, and cessation of blood flow. Microscopically, there was adherence of leukocytes to the vessel walls, and emigration through the walls, leukocytes were seen to adhere in the form of clumps. They reported that a similar reaction might follow the first injection These intravascular lesions may be considered as the preliminary stages of a thrombosis

Conclusions

It must be realized that postvaccinal encephalitis is only one of a number of diseases which all present a comparable histological appearance, demyelination being the main feature For example, similar conditions may complicate measles, smallpox, influenza, antirabies treatment, and perhaps varicella, these have all been referred to elsewhere Perivascular demyelination can also be produced experimentally by injection of coagulants and oils, which cause intravascular thrombosis (Putnam, McKenna, and Morrison, 1931, Putnam, 1935; Hoefer, Putnam, and Gray, 1938) In addition, we should mention that certain "spontaneous" conditions also resemble postvaccinal encephalitis, e g, Devic's disease, Schilder's disease, acute disseminated encephalomyelitis, and disseminated sclerosis Of recent years, much active work has been carried out on the etiology of demyelinating diseases Personally we feel that such work may eventually furnish the solution to the etiology, not only of disseminated sclerosis itself, but also of postvaccinal and the other infective forms of encephalomyelitis It is outside the scope of this book to describe this work in detail (see Putnam, 1935–6, 1937). We may, however, mention that

Hurst (1942) has suggested that the demyelination induced by chemicals is produced by repeated periods of anoxia. He has produced a continuous range of lesions ranging from necrosis to demyelination merely by varying the inoculum. It is probable that a number of agents, some viruses, some chemical substances, some bacteria, and some as yet unidentified, have the property of causing demyelination. Some of these agents may cause demyelination by a direct action on the myelinated tissue, and it is possible that the viruses act by causing the blood to clot more readily, or by inducing anoxia. The resultant vascular thromboses produce the characteristic histological picture of demyelination. It is possible that the primary factor in causing the thrombosis may be of an allergic character.

SECTION 4. ANTHROPOD-SPREAD AND OTHER TROPICAL INFECTIONS

CHAPTER XXXVI

RIFT VALLEY FEVER

Rift Valley fever or enzootic hepatitis was first described by Daubney, Hudson, and Garnham in 1931. These workers found the disease in Kenya Colony among sheep, and at the same time recorded its experimental transmission to man. In all probability the condition was noticed earlier by Montgomery (1913), who recorded an outbreak of a similar disease causing a 90 per cent mortality among lambs at a government farm at Naivasha in Kenya. The 1930 outbreak, which was described by Daubney and his coworkers, occurred on a farm situated at an altitude of 5,500 to 6,000 feet extending northwards from the shores of Lake Naivasha in the Rift Valley. About 3,500 lambs and 1,200 ewes died from the disease, and the mortality attained a figure of 95 per cent. among the 3 to 7 days' old lambs (see also Findlay and Daubney, 1931).

Rift Valley fever has been noticed in Kenya, Uganda, Anglo-Egyptian Sudan, French Sudan, and French Equatorial Africa (Findlay, Stefanopoulo, and MacCallum, 1936).

THE DISEASE IN MAN

Daubney, Hudson, and Garnham (1931) demonstrated the infectivity of Rift Valley fever virus for man by inoculating a human subject with a filtrate derived from infected sheep tissue. Later, Findlay (1932 *a*) recorded that many of the natives employed in herding sheep during the period of the enzootic also suffered from a short febrile condition resembling the experimental disease in man. Then, Schwentker and Rivers (1934) recorded a fatal case in a laboratory worker who contracted the disease and died following complication with thrombophlebitis. Kitchen (1934) described another laboratory infection, and subsequently Francis and Magill (1935) and Findlay (1932 *a*) drew attention to 6 other cases that were acquired in a similar fashion. In all, nearly 20 cases of laboratory infection have been recorded, even from virus passed hundreds of times in mice (Sabin and Blumberg, 1947). Curasson (1934) has suggested the possible occurrence of the disease in the French Sudan. The general course of the malady is that of a mild febrile illness and, according to Daubney, Hudson, and Garnham, at least 200 human cases have occurred in British East Africa, without complications or death.

Clinical Features

After an incubation period of 5 to 6 days, the symptoms of the disease develop suddenly. A wide variety of clinical manifestations is liable to be present, such as general malaise, headache, nausea, vomiting, shivering, rigors, shooting pains in the muscles and joints, particularly affecting the shoulder region and back, a sense of fullness over the liver, tenderness of the eyeballs, photophobia, mental confusion, vertigo, and epistaxis. The pyrexia varies from about 101 to 103° F., is of the so-called "saddle-back" type resembling that recorded in dengue, and may occasionally reach 105–6° F., the pulse rate being also increased. Usually, the disease only lasts for a few days and the convalescent period is short. Relapses have been reported (see Francis and Magill, 1935).

Clinical Pathology

The most characteristic feature is the presence of a leukopenia. A figure of 3,720 w.b.c. per *cmm* has been recorded by Francis and Magill, and the decline principally affects the polymorphonuclear leukocytes. Findlay (1932 *a*) has recorded the presence of occasional myelocytes and polymorphonuclear leukocytes possessing vacuolated nuclei. He also states that the leukopenia may persist into convalescence. Throughout the disease the patient's urine may appear to be normal in its color and constituents, containing neither blood, bile, nor casts. Findlay (1932 *a*), however, has mentioned a case in which the urine was of a deep yellow color but was not pathogenic for mice. Blood, or throat washings derived from patients during the height of the illness are infective for mice.

Pathology

The only fatal case on record is that reported in a laboratory worker who died from venous thrombosis, 45 days after the onset of infection. The acute stage of his illness only occupied the first week. At autopsy, clots were present principally in the inferior vena cava, and to a lesser extent in the saphenous and femoral veins. Chronic pleuritis together with old pulmonary infarcts and emboli were present in both lungs. The liver showed no abnormalities, and the virus could not be recovered from postmortem tissue. This was doubtless due to the active stage of the disease having subsided some considerable time prior to death (Schwentker and Rivers, 1934).

THE NATURAL DISEASE IN SHEEP

This is of a variable character, and the following signs have been recorded: vomiting, diarrhea, melena, mucopurulent nasal discharge, loss of appetite, abortion in pregnant animals, unsteady gait, and death usually within 24 hours of the onset of symptoms. The temperature is often normal.

The liver. Focal necrosis of this organ is the most striking feature of the disease. Small white foci of necrosis about 1 *mm* in diameter appear beneath the capsule of the liver, frequently surrounded by pin-point hemorrhages. Necrotic foci are evenly distributed throughout the organ, and when numerous they tend to coalesce, forming a diffuse necrotic lesion. There is, however, no sign of demarcation of necrotic areas from surrounding liver tissue. The liver is usually not increased in size but is occasionally engorged with blood.

The spleen is not enlarged, but shows numerous subcapsular pin-head hemorrhages, especially at the free border of the organ.

The kidneys. Hemorrhages and capillary arborescence have sometimes been recorded.

The lungs. Small, slightly raised areas which are oval in shape and an inch or more in diameter occur on the surface of the organ.

Circulatory system. Subpericardial ecchymoses are common in the region of the coronary grooves or the ventricles of the heart. The mesenteric vessels are always strongly injected and engorged with blood.

Lymphatic glands in the mesentery may be enlarged and show cortical necrosis.

Alimentary tract. The lesions here are of variable character, the principal changes affecting the lower intestine being hyperemia, congestion, and in severer cases, hemorrhagic enteritis.

CHARACTERISTICS OF THE VIRUS

Pathogenicity to Animals

Other than its infectivity for the lamb, sheep, and the human subject, the virus has been shown to be pathogenic to a number of other species of animals (see

SECTION 4. ANTHROPOD-SPREAD AND OTHER TROPICAL INFECTIONS

CHAPTER XXXVI

RIFT VALLEY FEVER

RIFT Valley fever or enzootic hepatitis was first described by Daubney, Hudson, and Garnham in 1931. These workers found the disease in Kenya Colony among sheep, and at the same time recorded its experimental transmission to man. In all probability the condition was noticed earlier by Montgomery (1913), who recorded an outbreak of a similar disease causing a 90 per cent. mortality among lambs at a government farm at Naivasha in Kenya. The 1930 outbreak, which was described by Daubney and his coworkers, occurred on a farm situated at an altitude of 5,500 to 6,000 feet extending northwards from the shores of Lake Naivasha in the Rift Valley. About 3,500 lambs and 1,200 ewes died from the disease, and the mortality attained a figure of 95 per cent among the 3 to 7 days' old lambs (see also Findlay and Daubney, 1931).

Rift Valley fever has been noticed in Kenya, Uganda, Anglo-Egyptian Sudan, French Sudan, and French Equatorial Africa (Findlay, Stefanopoulo, and MacCallum, 1936).

THE DISEASE IN MAN

Daubney, Hudson, and Garnham (1931) demonstrated the infectivity of Rift Valley fever virus for man by inoculating a human subject with a filtrate derived from infected sheep tissue. Later, Findlay (1932 *a*) recorded that many of the natives employed in herding sheep during the period of the enzootic also suffered from a short febrile condition resembling the experimental disease in man Then, Schwentker and Rivers (1934) recorded a fatal case in a laboratory worker who contracted the disease and died following complication with thrombophlebitis Kitchen (1934) described another laboratory infection, and subsequently Francis and Magill (1935) and Findlay (1932 *a*) drew attention to 6 other cases that were acquired in a similar fashion In all, nearly 20 cases of laboratory infection have been recorded, even from virus passed hundreds of times in mice (Sabin and Blumberg, 1947) Curasson (1934) has suggested the possible occurrence of the disease in the French Sudan The general course of the malady is that of a mild febrile illness and, according to Daubney, Hudson, and Garnham, at least 200 human cases have occurred in British East Africa, without complications or death

Clinical Features

After an incubation period of 5 to 6 days, the symptoms of the disease develop suddenly. A wide variety of clinical manifestations is liable to be present, such as general malaise, headache, nausea, vomiting, shivering, rigors, shooting pains in the muscles and joints, particularly affecting the shoulder region and back, a sense of fullness over the liver, tenderness of the eyeballs, photophobia, mental confusion, vertigo, and epistaxis The pyrexia varies from about 101 to 103° F, is of the so-called "saddle-back" type resembling that recorded in dengue, and may occasionally reach 105–6° F, the pulse rate being also increased Usually, the disease only lasts for a few days and the convalescent period is short. Relapses have been reported (see Francis and Magill, 1935)

brane, and the appearance of acidophilic material within the nucleoplasm In fresh tissue the latter may be stained by vital dyes such as dilute water-soluble eosin, methylene blue, neutral red, or phloxine red Janus green B and osmic acid exert no effect upon them Findlay states that the intranuclear inclusions of Rift Valley fever are dissolved by 0 1 per cent. acetic acid or 1 per cent ammonia; moreover, he adds that their existence in fresh tissue militates against their being artefacts in origin. Chemical tests have failed to disclose the nature of their composition, as they are neither blackened by osmic acid, nor can they be stained with sudan III, Scharlach R, or Nile blue sulfate in frozen sections They give a negative reaction for chromatin by the Feulgen technique, and also a negative Bensley-MacCallum for masked iron. The following is a list of stains used by Findlay for demonstrating intranuclear inclusions of Rift Valley fever iron hematoxylin and eosin, Giemsa, eosin and methylene blue, phloxine and methylene blue, resorcin fuchsin, phosphotungstic acid hemotoxylin, Mallory's stain, Castañeda's stain, neutral red and neutral gentian violet.

For work bearing on micro-incineration studies carried out in Rift Valley fever the reader is referred to the studies of Horning (1934).

Neurotropic Strain of Rift Valley Fever Virus

Mackenzie and Findlay (1936) passaged the virus 30 times intracerebrally through mice. By this method they succeeded in producing a neurotropic strain of virus which possessed a fixed affinity for nervous tissue, and such a strain, when injected intracerebrally in mice, produced encephalomyelitis without liver necrosis. Rhesus monkeys were also infected with this strain by intracerebral or intranasal inoculation. Rabbits and guinea-pigs were apparently insusceptible (Mackenzie, Findlay, and Stern, 1936)

Morphology, Size, and Filtrability of the Virus

This is one of the smallest viruses known, and some of the earliest experiments indicated this fact Thus Daubney and his colleagues found that it passed through the Pasteur-Chamberland L_{11} bougie, and occasionally even the L_{13} size. It also passed through the Berkfeld V, N, and W grades of candle at a pressure of 630 mm Hg (Findlay, 1932 a) Subsequently its size was more accurately measured by Broom and Findlay (1933), who filtered it through Elford's gradocol membranes and estimated its dimensions to lie between 23 and 35 mμ According to these figures, therefore, the virus is well beyond the limits of visibility of the ordinary microscope, and is even too small to be photographed by the ultraviolet light instrument (Findlay, 1933) Likewise all attempts to demonstrate the virus by staining have been without success (Mackenzie, 1933).

Cultivation

Cultivation was first performed by Mackenzie (1933), who used the method of Li and Rivers (1930), and employed a culture medium consisting of minced chicken embryo fragments suspended in Tyrode's solution (see Ch. XII) Cultures were put up in 5 c c Erlenmeyer flasks containing 5 c c of extract, incubated at 37° C for 3 days, and subcultivated by transferring 0 2 c c of the growth to a fresh medium In this way Mackenzie cultivated the virus through 13 passages, without either diminishing the infectivity of the material or altering its characteristics Saddington (1934) has also succeeded in cultivating the virus in tissue cultures

Preservation of Virus

Kitchen (1934) has preserved it for at least 8 months by mixing blood from ill mice with normal serum diluted 1/10, and by then desiccating the mixture *in vacuo*. During the course of our own studies on this virus we have preserved it by desic-

Findlay, 1932 *a*). In rhesus monkeys it produces a nonfatal illness, followed by recovery and protection from further attacks for at least 6 months afterwards.

The African monkeys, *Cercopithecus callitrichus*, *Erythrocebus patas*, and *Cercocebus fuliginosus*, fail to exhibit a febrile reaction when inoculated with Rift Valley virus, although it may persist for a few days in their blood Findlay (1932 *b*) pointed out that the relative insusceptibility of these species to infection was not due to the presence of antibodies in their blood, since antibodies only developed after inoculation South American monkeys, such as *Cebus fatuellus*, *C. chrysopus*, *Hapale jacchus*, and *H. penicillata*, were more susceptible and showed a febrile reaction following injection The virus can also be recovered from the blood of these species during a pyrexial period, and immune bodies are demonstrable in the blood of capuchin monkeys 14 days after injection. Cats exhibit a transient febrile illness. The virus is highly pathogenic and proves invariably lethal to mice, field voles (*Microtus agrestis*), wood mice (*Apodemus sylvaticus*), dormice (*Muscardinus avellanarius*), and golden hamsters (*Cricetus [mesocricetus] auratus*). In rats the virus causes a 50 per cent. mortality, and is of about the same degree of pathogenicity to the ferret (see Francis and Magill, 1935). The cow, goat, and gray squirrel suffer from a severe but nonfatal malady. Rabbits appear to be resistant, but may harbor the virus for a short time in their blood after infection. The guinea-pig, mongoose, hedgehog, tortoise, frog, hen, pigeon, and parakeet are resistant. Susceptible animals can be infected by any route of inoculation, and in pregnant animals the virus has been shown to be capable of passing through the placenta into the fetal circulation.

Morbid Histology of the Infected Liver

Lesions present in the sheep, goat, rat, mouse, monkey, squirrel, hamster, vole, and wood mouse have been carefully studied by Findlay (1933). The changes are either those affecting the cytoplasm or the nuclei of liver cells, and are as follows

Changes in the cytoplasm.

The initial lesion is focal necrosis of the liver, which may affect any area, but in the rhesus monkey it tends to be confined to the mid-zonal area of the lobule *In lambs, mice, rats, and other small rodents no such distinction* is possible, owing to the rapidity with which the infection spreads through the whole organ. For example, in [illegible] liver tissue left. [illegible] necrosis oc[illegible] bodies within the cytoplasm of individual liver cells. These structures are often surrounded by a clear space and may even be extruded from the liver cell, they tend to be best developed in the most resistant animals such as the adult sheep and goat, whereas they are less well marked in the susceptible mouse. Fatty degeneration and pigmentation are only occasionally seen in the rhesus monkey and are absent in other species *In the case of mice, 48 hours after infection the whole structure* of the liver lobule is destroyed, nuclei show karyorrhexis, the cytoplasm becomes vacuolated and contains a few remnants of mitochondria and nuclear chromatin. [illegible] apparatus were also investigated by Findlay, [illegible] the purpose, and found that all traces [illegible] liver cells at the end of 48 hours in infected mice.

Nuclear changes.

These changes in liver cells are a characteristic feature of the disease. They were originally observed *by Daubney and his coworkers, and later extensively* reinvestigated by Findlay (1932 *a*) The essential changes are margination of the chromatin which becomes distributed inside the periphery of the nuclear mem-

moreover, the characteristic liver necrosis evident in Rift Valley infection of laboratory animals bears a striking resemblance to human liver necrosis caused by yellow fever virus There is, however, no reason to believe that Rift Valley fever produces extensive liver lesions in man, at least, in those cases which have been quoted in the literature, it has not caused sufficient damage to be recognizable *clinically*.

Dengue Fever

Findlay (1932 c) investigated this problem and found that these conditions were entirely distinct and separate pathological entities. Thus he successfully demonstrated, by means of cross neutralization tests, that the monkey *Silenus rhesus* when immunized against dengue was not immune to Rift Valley virus In the same way, monkeys immunized against Rift Valley fever could be infected with dengue virus Also, mice injected with dengue virus were not immune to Rift Valley fever virus

Yellow Fever

The points of similarity and dissimilarity existing between this and Rift Valley fever virus are summarized in an excellent account of the subject in the work of Findlay and MacCallum (1937) The features of differentiation may be summarized thus Both viruses are exceedingly small in size, but yellow fever virus, which measures 18 to 27 mμ (see Broom and Findlay, 1933, and Bauer and Hughes, 1935), is the smaller of the two, however, Findlay and MacCallum (1937) have accepted these figures with reserve, in view of the margin of error involved when estimating the size of the smaller viruses by ultrafiltration Rift Valley fever virus is highly infective to sheep, goats, and small rodents, whereas yellow fever virus does not attack these species *In vitro* virus neutralization tests performed with immune sera derived from either condition have failed to reveal the existence of cross reaction between these agents *In vivo* tests have shown that monkeys recovering from Rift Valley fever are susceptible to yellow fever virus and vice versa, moreover a laboratory worker who contracted an attack of yellow fever, 3 years later developed Rift Valley fever

These viruses have many features in common, however, and clinically Rift Valley fever resembles mild yellow fever

Certain species of monkey appear to exhibit the same degree of susceptibility to both infections, according to Findlay (1932 a, 1933) In liver tissue, acidophilic intranuclear inclusions as well as Councilman lesions appear in both diseases Likewise, virus possessing neurotropic properties is obtainable from either agent by repeated intracerebral passage (see MacKenzie, Findlay, and Stern, 1936)

Both yellow fever and Rift Valley fever confer lasting immunity to man following one attack Like yellow fever, Rift Valley fever appears to be transmitted by mosquitoes of the aedes genus (Daubney and Hudson, 1933), and Daubney and Hudson (1932) also showed that the virus was able to survive for 7 days in the engorged nymph of the species *Rhipicephalus appendiculatus* In view of these findings, Findlay and MacCallum (1937) have ventured to suggest that both viruses may have originated from some common ancestral form, although geographically their distributions vary The classification of these two diseases has also been discussed by Broquet (1932)

Influenza

The difficulty of differentiating Rift Valley fever from acute influenza on purely clinical grounds has been emphasized in a report by Francis and Magill (1935) Both diseases exhibit many features in common, for example, the abrupt onset, short incubation period, aches and muscular pains, together with a marked leukopenia

cating mouse liver tissue *in vacuo* over calcium chloride, according to Craigie's method (1931). Findlay (1932 *a*) showed that lamb's blood, to which 0.5 per cent. carbolic acid was added, stored at 4° C, retained its infectivity for mice for 6 months. After 8 months' in oxalate-carbolic-glycerol there was some loss of virulence.

Resistance to Heat

Virus in blood is killed in 40 minutes at 56° C. (Findlay, 1932 *a*).

IMMUNITY REACTIONS IN MAN AND ANIMALS

Complement fixing and virus neutralizing antibodies develop in the first week of illness, and increase markedly in the second week (Broom and Findlay, 1932; Schwentker and Rivers, 1934; Findlay, 1936). Virus neutralizing antibodies have been described 12 years after recovery from a laboratory infection (Sabin and Blumberg, 1947).

Apparently neutral mixtures can be reactivated by dilution, or inoculation nasally instead of peritoneally (Findlay, 1936). The immunization of mice against Rift Valley fever virus has been described by Mackenzie (1935).

An Interference Phenomenon

Findlay and MacCallum (1937) have described the existence of a most interesting phenomenon relating to the apparently antagonistic action of Rift Valley fever and yellow fever viruses when introduced simultaneously into the same animal They have shown that the inoculation of a mixture of both viruses into rhesus monkeys results in protection of 7 out of 10 animals Likewise, a single inoculation of mice with neurotropic yellow fever virus and pantropic Rift Valley fever virus delays their death and even saves a few from it. The protective action is absent, however, if Rift Valley fever virus is injected 24 hours previously. The effect of substituting fowl-pest virus (which is nonpathogenic to mice) was also tried in place of yellow fever virus, but this failed to afford the same degree of protection against Rift Valley fever infection.

In explanation of these findings, Findlay and MacCallum have suggested that, when certain cells are occupied by an actively multiplying virus, they cannot be invaded by other virus particles. They also draw an analogy between this phenomenon and the occurrence of a somewhat similar phenomenon in respect of plant viruses. In the case of plants, it has been shown that a feebly pathogenic agent will afford protection to a plant when infected with a more virulent one, provided that the two viruses are generically related, see Thung (1931), Salaman (1933), Kunkel (1934), Holmes (1934), Ainsworth (1934), Caldwell (1935), McKinney (1935), and Price (1935) The interference phenomenon occurs also in poliomyelitis and influenza (Chs. LXXXI and LIX)

LABORATORY DIAGNOSIS OF RIFT VALLEY FEVER

During a febrile attack the patient's blood should be withdrawn and inoculated subcutaneously or intraperitoneally in a mouse If the animal dies, its liver and blood should first be examined to exclude the presence of bacteria, by aerobic and anaerobic methods of cultivation If the result is negative, then histological sections of liver should be stained and searched for presence of intranuclear inclusion bodies and other changes characteristic of Rift Valley fever. Serum may be injected cerebrally in mice Acute and convalescent phase serum should be tested for the existence of virus neutralizing antibodies

RELATIONSHIP TO OTHER VIRUS DISEASES

Rift Valley fever in man is of interest on account of its clinical similarities to dengue fever on the one hand and epidemic influenza on the other. Pathologically,

moreover, the characteristic liver necrosis evident in Rift Valley infection of laboratory animals bears a striking resemblance to human liver necrosis caused by yellow fever virus There is, however, no reason to believe that Rift Valley fever produces extensive liver lesions in man, at least, in those cases which have been quoted in the literature, it has not caused sufficient damage to be recognizable clinically

Dengue Fever

Findlay (1932 *c*) investigated this problem and found that these conditions were entirely distinct and separate pathological entities Thus he successfully demonstrated, by means of cross neutralization tests, that the monkey *Silenus rhesus* when immunized against dengue was not immune to Rift Valley virus In the same way, monkeys immunized against Rift Valley fever could be infected with dengue virus Also, mice injected with dengue virus were not immune to Rift Valley fever virus

Yellow Fever

The points of similarity and dissimilarity existing between this and Rift Valley fever virus are summarized in an excellent account of the subject in the work of Findlay and MacCallum (1937). The features of differentiation may be summarized thus Both viruses are exceedingly small in size, but yellow fever virus, which measures 18 to 27 mμ (see Broom and Findlay, 1933, and Bauer and Hughes, 1935), is the smaller of the two, however, Findlay and MacCallum (1937) have accepted these figures with reserve, in view of the margin of error involved when estimating the size of the smaller viruses by ultrafiltration Rift Valley fever virus is highly infective to sheep, goats, and small rodents, whereas yellow fever virus does not attack these species *In vitro* virus neutralization tests performed with immune sera derived from either condition have failed to reveal the existence of cross reaction between these agents *In vivo* tests have shown that monkeys recovering from Rift Valley fever are susceptible to yellow fever virus and vice versa, moreover a laboratory worker who contracted an attack of yellow fever, 3 years later developed Rift Valley fever.

These viruses have many features in common, however, and clinically Rift Valley fever resembles mild yellow fever.

Certain species of monkey appear to exhibit the same degree of susceptibility to both infections, according to Findlay (1932 *a*, 1933) In liver tissue, acidophilic intranuclear inclusions as well as Councilman lesions appear in both diseases Likewise, virus possessing neurotropic properties is obtainable from either agent by repeated intracerebral passage (see Mackenzie, Findlay, and Stern, 1936).

Both yellow fever and Rift Valley fever confer lasting immunity to man following one attack Like yellow fever, Rift Valley fever appears to be transmitted by mosquitoes of the aedes genus (Daubney and Hudson, 1933), and Daubney and Hudson (1932) also showed that the virus was able to survive for 7 days in the engorged nymph of the species *Rhipicephalus appendiculatus*. In view of these findings, Findlay and MacCallum (1937) have ventured to suggest that both viruses may have originated from some common ancestral form, although geographically their distributions vary. The classification of these two diseases has also been discussed by Broquet (1932)

Influenza

The difficulty of differentiating Rift Valley fever from acute influenza on purely clinical grounds has been emphasized in a report by Francis and Magill (1935). Both diseases exhibit many features in common, for example, the abrupt onset, short incubation period, aches and muscular pains, together with a marked leukopenia.

CHAPTER XXXVII

DENGUE FEVER

Historical

According to Hirsch (1883) this disease has received many different names Thus the Spaniards called it *dengue*, corresponding in meaning to the French word *minauderie* and the English word *dandy* The word *colorado* was also applied by the Spaniards as a descriptive term The English and Americans have called it *break-bone* and *broken-wing*, the French *giraffe* and *bouquet* (whence the English corrupt *bucket*), and the Brazilians have named it polka fever.

Hirsch states that the earliest accounts of dengue fever were those given by Galberti of Egypt in 1779, by Bylon of Batavia in 1779, and by Rush of Philadelphia in 1780. Later, the disease appeared in the West Indies and shores of the Gulf of Mexico, where it was called dengue fever by the local physicians It was not, however, until dengue broke out in the Eastern Hemisphere in 1871–3 that the disease received universal recognition as a distinct clinical entity.

It should be mentioned, however, that the accurate clinical diagnosis of dengue fever is by no means always an easy matter. For example, sporadic atypical cases of dengue may sometimes present clinical signs and symptoms simulating a variety of other febrile illnesses, e g , pappataci fever, malaria, mild yellow fever, and Rift

golaise are no longer regarded as separate entities but accepted as atypical cases of dengue fever

years a number

etiology especial

Ghosh, 1942; Fir

1945). The char

end of this chapter.

Dengue is now known to be transmitted by *Aedes aegypti* (*Stegomyia fasciata*), the mosquito that is also responsible for the spread of yellow fever. Since both diseases are disseminated by a common insect vector, the precise geographical distribution of each malady, and likewise of *A. aegypti*, becomes a matter of considerable importance, especially with regard to modern air travel.

Lumley (1943) has published a useful review of the disease

EPIDEMIOLOGY

The rapidity with which dengue fever spreads is popularly regarded as being second only to that of epidemic influenza. For example, Armstrong (1923) states that at Austin, Texas, in 1885, out of 22,000 persons, 16,000 were attacked At Cairo in 1880 four-fifths of the inhabitants were affected, and during the 1818 epidemic at Lima in Peru only a few of the 70,000 inhabitants escaped (Hirsch, 1883). Armstrong (1923) records an outbreak of dengue at Monroe, La , in 1922, among the poorer members of the Negro community, during which 1,000 inhabitants were attacked. Millous (1929) reported an outbreak of 1,000 cases in Cochin-China in 1927, and Hargrave (1931) a similar epidemic in American Samoa, during which 2,842 cases were observed in 2 months

The importance of dengue from the standpoint of military hygiene can be appreciated, since large numbers of soldiers or sailors are liable to be affected (Kennedy, 1912; Basset Smith, 1923, Giordano, 1924, Perves, 1927). The disease pre-

sented a definite problem in the Second World War, especially on the Pacific fronts (Cavanagh, 1943; Hyman, 1943; Carson, 1944; Kisner and Lisansky, 1944; Stewart, 1944; Johnson, Martin, and Breslow, 1946).

The Rôle of *Aedes aegypti* and other Mosquitoes

Graham (1903) was probably the first worker to suspect the mosquito as the vector of dengue fever, and he stated that the disease was caused by a protozoan parasite which was transmitted by *Culex fatigans* Although he appreciated the part played by the mosquito, he failed to identify the correct species and, moreover, was mistaken with regard to the existence of a protozoan parasite in certain fluids Later Bancroft (1906) in Brisbane succeeded in infecting 2 human volunteers by exposing them to the bites of infected *Aedes aegypti.* The results were sufficiently convincing, but they have been criticized by Armstrong (1923) on the grounds that dengue was prevalent in the locality in which the experiments were performed. In their classical experiments Cleland, Bradley, and McDonald (1918, 1919) excluded this fallacy by transporting *A. aegypti* from the endemic area to Sydney, which was free from the disease, and where they infected 4 volunteers by permitting them to be bitten by the insects. Subsequently, the work of Cleland and his associates was confirmed by many independent investigators, and the part played by *Aedes* in the propagation of dengue established beyond all doubt.

The next matter to receive the attention of various workers was an inquiry to determine whether dengue virus was carried by *A aegypti* alone or by other mosquitoes also. Numerous species were studied by various workers, and although the *reports are unanimous in their verdict regarding the rôle of A. aegypti* as a vector, there seems to be some doubt concerning the ability of other species to [illegible] Craig (1920), *Culex fatigans* [illegible] ns colleagues (1916) denied [illegible] r (1928), Kligler and Aschner (1928), Blanc and Caminopetros (1928, 1930 *a*, and Siler, Hall, and Hitchens (1925 *a, b*), all found that C. *fatigans* was not a vector of dengue fever. Blanc and Caminopetros (1930 *a, b*) even went so far as to suggest that in Greece and Macedonia *A aegypti* was the only mosquito which transmitted the disease The weight of data, therefore, supports the view that C. *fatigans* does not actively participate in the spread of dengue.

In Manila another mosquito, *Aedes albopictus* (Skuse), was found to be equally effective in transmitting dengue fever (Simmons, St. John, and Reynolds, 1930). In Sumatra *A albopictus* was also found to be the insect vector of the disease by Snijders, Dinger, and Schuffner (1931). These workers succeeded in transporting infected *A albopictus* from Sumatra to Amsterdam, and were there able to reproduce dengue in human volunteers by subjecting them to the bites of the insects In Formosa, Morishita (1925) has accused *Stegomyia scutellaris* Walk and also *Armigeres (Desvoidea) obturbans* Walk In New Guinea, the forest-living *Aedes stegomyia scutellaris Walk.* has been incriminated, and shown to be capable of infecting volunteers in Sydney (Mackerras, 1946) Taylor (1943) has published a useful account of the entomology of *Aedes aegypti* and *A albopictus* Usinger (1944) describes *the entomology in Honolulu Chandler and Rice (1923)* have reported positive results in experiments with *Aedes argenteus* in Texas

During the course of experiments primarily designed to ascertain which insect vector is responsible for the dissemination of dengue fever, valuable data have emerged regarding the fate of the virus in different mosquitoes Results reveal that the transmission of dengue fever from man to mosquito and from the latter to a susceptible individual is not a mechanical process For example, it has been proved that species of *Aedes* which had been fed on the blood of patients were noninfective to man on the 2nd, 3rd, 4th and 6th days after they had been fed, but from the 7th day onward the insects became capable of infecting human volunteers

(see Schule, 1928, and Blanc, 1938) The length of this "extrinsic" incubation period usually varied from 7 to 10 days and appeared to depend on the prevailing temperature, as it could be diminished by heat and increased by cold (Schule, 1928). Below 18° C. infected *Aedes* ceased to transmit the virus, and this observation of Blanc and Caminopetros (1929 *a*) is of considerable importance, since it has long been recognized that the advent of frost speedily brings outbreaks of dengue to a close (see Armstrong, 1923). Interrupted feeding has been referred to by Chandler and Rice as a possible method whereby the disease can be spread. Schule (1928), on the contrary, failed to confirm this observation and he was unable to transmit dengue by performing interrupted feeding tests with 18 mosquitoes

Simmons, St. John, and Reynolds (1930) found that it took 13 to 22 days after feeding on a patient before *A. albopictus* became infective to man. Once infected, an *Aedes* may remain infective for a considerable time, and Blanc and Caminopetros (1929 *a*) demonstrated that mosquitoes could retain their infectivity for as long as 174 days Under the circumstances, it seems possible that once a mosquito becomes infected, it may remain so for the remainder of its life It is also conceivable that the insect may only be infective at certain seasons of the year and not at others, for Blanc and Caminopetros (1929 *a*) discovered that infected *A. aegypti* were noninfective in the months of January, February, and March, but became infective from April onwards Such entomological studies are of profound practical importance to the medical epidemiologist, as they supply valuable information concerning the dissemination of dengue among a community. It also explains many of the hitherto unsolved problems regarding the sudden spread of the disease which is, of itself, noncontagious in character. Thus, Craig (1920), in discussing the work of Ashburn and Craig (1907 *a*, *b*), clearly showed how cases of dengue fever could be safely nursed in the general wards of a hospital without fear or risk of infecting adjacent patients, provided that the dengue cases were placed under cover of mosquito netting These results undoubtedly add further testimony to the theory of mosquito transmission of the disease, but they fail to explain why a large number of persons suddenly develop the disease within a comparatively short time. Under the circumstances, the only satisfactory answer to the problem would appear to lie in the possibility of a large number of mosquitoes becoming infective at once Manoussakis (1931) believes that the essential factor is the presence of a large number of infected mosquitoes. This occurs gradually over a period of time, for example, in an endemic area, at the beginning of the warm weather, a few sporadic cases of dengue follow upon the bites of infective mosquitoes More of the insects then become infective by feeding on such patients, and in turn fresh cases of dengue develop, accompanied by a corresponding rise in the population of infected mosquitoes, so that at the height of the hot season there is a large population of infected *A. aegypti*. Thereafter, the size and magnitude of the ensuing epidemic are merely governed by the number of susceptible subjects existing in the locality. According to Hanson (1936), fewer mosquitoes are necessary for the spread of dengue among the members of a community than are required for the dissemination of yellow fever. Thus, Hanson has pointed out that, whereas epidemics of dengue could occur when relatively few mosquitoes were present, he has observed the decline of

bers of *Aedes* were still on t

due to the fact that in coun

munity is complete and of lifelong duration, whilst dengue immunity only lasts from 1 to 7 years, and consequently more persons of a given population may be susceptible to dengue than yellow fever.

Efforts have been made to determine whether dengue virus can be transferred from an infected to a healthy mosquito St. John, Simmons and Reynolds (1930) state that the transference is possible under experimental conditions. It was also shown that the virus could be transferred from one mosquito to another by copula-

sented a definite problem in the Second World War, especially on the Pacific fronts (Cavanagh, 1943, Hyman, 1943, Carson, 1944, Kisner and Lisansky, 1944, Stewart, 1944; Johnson, Martin, and Breslow, 1946).

The Rôle of *Aedes aegypti* and other Mosquitoes

Graham (1903) was probably the first worker to suspect the mosquito as the vector of dengue fever, and he stated that the disease was caused by a protozoan parasite which was transmitted by *Culex fatigans*. Although he appreciated the part played by the mosquito, he failed to identify the correct species and, moreover, was mistaken with regard to the existence of a protozoan parasite in certain fluids. Later Bancroft (1906) in Brisbane succeeded in infecting 2 human volunteers by exposing them to the bites of infected *Aedes aegypti*. The results were sufficiently convincing, but they have been criticized by Armstrong (1923) on the grounds that dengue was prevalent in the locality in which the experiments were performed In their classical experiments Cleland, Bradley, and McDonald (1918, 1919) excluded this fallacy by transporting *A. aegypti* from the endemic area to Sydney, which was free from the disease, and where they infected 4 volunteers by permitting them to be bitten by the insects Subsequently, the work of Cleland and his associates was confirmed by many independent investigators, and the part played by *Aedes* in the propagation of dengue established beyond all doubt.

The next matter to receive the attention of various workers was an inquiry to determine whether dengue virus was carried by *A. aegypti* alone or by other mosquitoes also. Numerous species were studied by various workers, and although the reports are unanimous in their verdict regarding the rôle of *A aegypti* as a vector, there seems to be some doubt concerning the ability of other species to transmit the disease. According to Graham (1903) and Craig (1920), *Culex fatigans* was capable of infecting volunteers, but Cleland and his colleagues (1916) denied that *C. fatigans* could transmit dengue. Similarly, Kligler (1928), Kligler and Aschner (1928), Blanc and Caminopetros (1928, 1930*a*, and Siler, Hall, and Hitchens (1925 *a*, *b*), all found that C. *fatigans* was not a vector of dengue fever. Blanc and Caminopetros (1930 *a*, *b*) even went so far as to suggest that in Greece and Macedonia *A aegypti* was the only mosquito which transmitted the disease The weight of data, therefore, supports the view that *C fatigans* does not actively participate in the spread of dengue.

In Manila another mosquito, *Aedes albopictus* (Skuse), was found to be equally effective in transmitting dengue fever (Simmons, St. John, and Reynolds, 1930). In Sumatra *A albopictus* was also found to be the insect vector of the disease by Snijders, Dinger, and Schuffner (1931) These workers succeeded in transporting infected *A albopictus* from Sumatra to Amsterdam, and were there able to reproduce dengue in human volunteers by subjecting them to the bites of the insects. In Formosa, Morishita (1925) has accused *Stegomyia scutellaris* Walk and also *Armigeres (Desvoidea) obturbans* Walk In New Guinea, the forest-living *Aedes stegomyia scutellaris Walk* has been incriminated, and shown to be capable of infecting volunteers in Sydney (Mackerras, 1946) Taylor (1943) has published a useful account of the entomology of *Aedes aegypti* and *A albopictus* Usinger (1944) describes the entomology in Honolulu Chandler and Rice (1923) have reported positive results in experiments with *Aedes argenteus* in Texas

During the course of experiments primarily designed to ascertain which insect vector is responsible for the dissemination of dengue fever, valuable data have emerged regarding the fate of the virus in different mosquitoes Results reveal that the transmission of dengue fever from man to mosquito and from the latter to a susceptible individual is not a mechanical process For example, it has been proved that species of *Aedes* which had been fed on the blood of patients were noninfective to man on the 2nd, 3rd, 4th and 6th days after they had been fed, but from the 7th day onward the insects became capable of infecting human volunteers

In the northern sector the disease has been noted extensively in Texas. cases have been reported from Fort Worth (King, 1907, and Graves, 1908); from Brownsville (Goldberger and McCoy, 1907); and from Galveston (Rice, 1922, 1923). In Florida, epidemics have been mentioned as occurring in Jacksonville (Porter, 1894), in Miami (Griffitts and Hanson, 1936), and in Key West (Porter, 1894). The disease has been reported in Louisiana by Scott (1923), in the Isthmus of Panama by Sutton (1904), and Carpenter and Sutton (1905), in Dutch Guiana by Bonne (1918), and in Bogota, Colombia, by Tascon (1924). Many of the large and smaller islands off the American coast have also been involved and reports of epidemics are recorded in Bermuda by Meagher (1916), in Cuba by Allen (1908), and Guiteras and Cartaya (1906); in Puerto Rico the 1915 epidemic was described by King (1917), and a smaller outbreak involving 100 persons in St. Thomas island is mentioned by Lane (1918).

South of the equator, cases have been reported from Ecuador by Carbo-Noboa (1926), and in the Argentine by Kraus (1916), who states that the disease was probably imported directly from Spain.

Australasia.

Outbreaks of the disease have occurred in New South Wales in the years 1898, 1906, 1916, and 1926 (see Ferguson, 1926, Goldsmid and Crosse, 1916, and Goldsmid, 1917). North Queensland was affected in 1897 (Hare, 1898), and Brisbane in 1905 (Robertson *et al.*, 1905). Subsequently cases were described in this area by O'Brien (1908), Scott (1911), Davidson (1911), and more recently an outbreak was recorded by McCallum and Dwyer (1927). An epidemic in 1927–8 at Port Darwin has been recorded by Murray (1931). Later papers are those of Walker *et al.* (1942), Lumley (1943), Zussman (1944). It occurs in New Guinea (Mackerras, 1946)

Pacific Islands.

Numerous cases have been recorded from time to time as occurring in this part of the globe In the Philippines they have been reported by Bell (1906) and Jones (1909), in New Caledonia by Nicolas (1927), and in Nouméa (New Caledonia) by Cozanet (1910). In the Fiji Islands a large epidemic was observed in 1885 by Skottowe (1890), and a later recrudescence in 1907 by Montague (1908). In American Samoa, in 1930, an epidemic occurred during which 2,842 cases developed within 2 months (Hargrave, 1931). The Hawaiian Islands were affected by dengue in 1903, and Wilson (1904) has published an account of this outbreak. From 1912 onward the disease was rare, but there was a sharp outbreak in 1943, terminated by vigorous anti-Aedes measures (Wilbar, 1947).

Perry (1948) concludes that *A aegypti* is the main vector in the S Pacific.

Greece, Turkey, Palestine, Syria, and neighboring country.

These areas may be regarded as the home of the disease, and Blanc and Caminopetros (1930*a*) have given a good account of the clinical, epidemiological, and experimental aspects of dengue fever as met with in these parts, and their paper [illegible]

reader to a few.

At Athens and in Greece during 1927–8 about 20,000 are reported to have suffered (Copanaris, 1928, and Tsiminakis, 1930). In Constantinople cases have been reported by Siotis (1889), Maléas (1889), Spadaro (1890–1), Zohrab (1890), and Stefko (1917), who has recorded the 1916 epidemic in Turkey. In the Dardanelles and Macedonia it was reported by Armand-Delille (1916), in Rhodes by Poggi (1929), in Cyprus by Caragéorgiadès (1889), in Naples by Cantani (1890), and

tion. Simmons *et al.* (1931) suggested, however, that although this was possible experimentally it was unlikely that the virus could be transmitted from insect to insect in this manner in nature. Under artificial conditions, St. John, Simmons, and Reynolds (1930) were able to infect healthy *Aedes* by inducing them to feed through guinea-pig's skin on a mixture of blood and dengue virus. Such artificially infected mosquitoes were then proved to transmit the virus when they bit volunteers.

The distribution of virus in the body of infected *A. aegypti* has been investigated by Holt and Kintner (1931). These workers allowed laboratory-bred mosquitoes to feed on cases of dengue fever, and 20 days later they dissected the insects, and injected the various organs into human volunteers. From this work, the virus was found to be present in the salivary glands, ovaries, testes, stomach, intestines, and the legs of infected mosquitoes, and volunteers who had been inoculated with each of these parts developed dengue fever in due course. Dengue virus, therefore, appears to be evenly distributed throughout the tissues of the mosquito, a finding which has led Holt and Kintner to the conclusion that during the sojourn of the virus in the body of the vector it undergoes simple multiplication, and probably does not undergo cyclical development. Further support of this view is supplied by the fact that the virus can be serially propagated through at least 4 human passages without any apparent attenuation in virulence (Cleland, Bradley, and McDonald, 1919). Neither did alternate passage between man and mosquito for 6 generations appear to influence its pathogenicity (Siler, Hall and Hitchens, 1926).

In summarizing the literature on the mosquito-transmission of dengue virus, it seems to be universally accepted that under normal circumstances *Aedes aegypti* is the commonest natural vector of the disease, and once infected the insect may so remain for the remainder of its life. On the other hand, the virus does not seem to survive long in certain mosquitoes, such as *Culex fatigans*, since Simmons, St John, and Reynolds (1931) report that this mosquito digests and kills the virus in 14 days. It would be unwise, however, to assume that *C. fatigans* or, indeed, any blood-sucking insect is totally incapable of transmitting dengue because it may well do so, merely by the mechanical transference of blood during interrupted feeding (Simmons, St. John, and Reynolds, 1931). The positive result reported by Craig (1920) may have been due to this cause, as the culex which was induced to bite a volunteer had fed upon a patient only some 2 days previously. The virus may have been carried by the mosquito for this short time. Likewise, *A. aegypti* may propagate infection by mechanical inoculation of infected blood as well as by the natural medium of infective saliva.

Lumley (1943) summarizing the experimental work, mostly alluded to above, concludes that patients can infect *Aedes* from 1 day before to 5 days after the onset of illness, the average "extrinsic" incubation in the mosquito is 8 days, and once infective it may remain so for life, Aedes probably do not infect their eggs

Control of Dengue

The control is largely a question of antimosquito measures, such as clearing away unnecessary water containers, oiling, and spraying, patients should be nursed under nets (Walker *et al.*, 1942, Gilbertson, 1945). DDT sprays are recommended

Geographical Distribution of Dengue Fever

Armstrong (1923) lists the main epidemics in various parts of the world. The disease is most prevalent in the following countries:

America.

The distribution of cases tends to be confined to a belt extending from 36° north to 35° south of the equator

In the northern sector the disease has been noted extensively in Texas: cases have been reported from Fort Worth (King, 1907, and Graves, 1908), from Brownsville (Goldberger and McCoy, 1907), and from Galveston (Rice, 1922, 1923). In Florida, epidemics have been mentioned as occurring in Jacksonville (Porter, 1894), in Miami (Griffitts and Hanson, 1936), and in Key West (Porter, 1894). The disease has been reported in Louisiana by Scott (1923), in the Isthmus of Panama by Sutton (1904), and Carpenter and Sutton (1905); in Dutch Guiana by Bonne (1918); and in Bogota, Colombia, by Tascon (1924). Many of the large and smaller islands off the American coast have also been involved and reports of epidemics are recorded in Bermuda by Meagher (1916), in Cuba by Allen (1908), and Guiteras and Cartaya (1906); in Puerto Rico the 1915 epidemic was described by King (1917); and a smaller outbreak involving 100 persons in St Thomas island is mentioned by Lane (1918).

South of the equator, cases have been reported from Ecuador by Carbo-Noboa (1926), and in the Argentine by Kraus (1916), who states that the disease was probably imported directly from Spain.

Australasia.

Outbreaks of the disease have occurred in New South Wales in the years 1898, 1906, 1916, and 1926 (see Ferguson, 1926, Goldsmid and Crosse, 1916, and Goldsmid, 1917). North Queensland was affected in 1897 (Hare, 1898), and Brisbane in 1905 (Robertson *et al.*, 1905) Subsequently cases were described in this area by O'Brien (1908), Scott (1911), Davidson (1911), and more recently an outbreak was recorded by McCallum and Dwyer (1927). An epidemic in 1927–8 at Port Darwin has been recorded by Murray (1931) Later papers are those of Walker *et al* (1942), Lumley (1943), Zussman (1944). It occurs in New Guinea (Mackerras, 1946).

Pacific Islands.

Numerous cases have been recorded from time to time as occurring in this part of the globe. In the Philippines they have been reported by Bell (1906) and Jones (1909), in New Caledonia by Nicolas (1927), and in Nouméa (New Caledonia) by Cozanet (1910) In the Fiji Islands a large epidemic was observed in 1885 by Skottowe (1890), and a later recrudescence in 1907 by Montague (1908) In American Samoa, in 1930, an epidemic occurred during which 2,842 cases developed within 2 months (Hargrave, 1931). The Hawaiian Islands were affected by dengue in 1903, and Wilson (1904) has published an account of this outbreak From 1912 onward the disease was rare, but there was a sharp outbreak in 1943, terminated by vigorous anti-Aedes measures (Wilbar, 1947).

Perry (1948) concludes that *A. aegypti* is the main vector in the S Pacific.

Greece, Turkey, Palestine, Syria, and neighboring country.

These areas may be regarded as the home of the disease, and Blanc and Caminopetros (1930 *a*) have given a good account of the clinical, epidemiological, and experimental aspects of dengue fever as met with in these parts, and their paper contains a map showing the distribution of *Aedes* in Greece The reports contained in medical literature describing outbreaks of dengue fever in these regions are too numerous to be cited individually, and it is, therefore, only possible to refer the reader to a few

At Athens and in Greece during 1927–8 about 20,000 are reported to have suffered (Copanaris, 1928, and Tsiminakis, 1930) In Constantinople cases have been reported by Siotis (1889), Maléas (1889), Spadaro (1890–1), Zohrab (1890), and Stefko (1917), who has recorded the 1916 epidemic in Turkey. In the Dardanelles and Macedonia it was reported by Armand-Delille (1916), in Rhodes by Poggi (1929), in Cyprus by Carageorgiadès (1889), in Naples by Cantani (1890), and

in other areas by Adrien (1918). The Smyrna epidemic of 1889 is recorded by Crediropoulos (1890), Diamantopulos (1890), and Stamatiades *et al.* (1890). About the same time Wortabet (1887) and De Brun (1889) noted it at Beirut in Syria. The disease has been described in Baghdad, Iraq (Fleming and French, 1947). Couvy (1921) described later epidemics in Beirut and Hitti and Khairallah (1946). In Palestine Masterman (1913) gives an account of the disease, and Dive (1927) noted it at Aden in Arabia.

Europe.

Apart from the above-mentioned areas of the continent in which dengue has been observed, cases have been reported at Lisbon by Tavares (1889), and in Vienna by Eugling (1922). The latter stated that the small outbreak which occurred in the summer of 1921 in Vienna was not due to infection acquired locally, but was introduced by Macedonian immigrants.

Africa.

The disease is widely distributed throughout this continent and cases have been reported in Egypt by Sandwith (1888), Phillips (1906), and Kamal (1928); in the Sudan by Balfour (1907), Saigh (1906), and Archibald (1917); in Zanzibar by Godding (1890), in East Africa by de Sousa (1924) and McCarthy and Brent (1943), and at Accra in the Gold Coast by Corson (1921). Cases have also been reported to occur among the French naval forces stationed at Dakar (see Bideau, 1925, Perves, 1927, 1928).

India.

Dengue is found throughout the country and cases have been mentioned as occurring in Sialkot by Fooks (1908), in Calcutta by Kennedy (1912), in Meerut by Khan (1913), in Guzerat by Dalsukhram (1913), the Punjab by Farrer (1924). Other accounts are to be found in the writings of Rogers (1909), Megaw (1919), and Barrand (1928).

In Ceylon the disease is also relatively common, and cases have been recorded by Spaar (1925).

The Far East.

Dengue has an extensive distribution throughout the Far East of the globe. Cases have been reported in Burma by Pridmore (1902), and in Rangoon by Jafar and Singh (1932), in Penang by Skae (1902), in Indo-China by Vassal and Brochet (1909), in Cochin-China by Lalluyaux (1914), who gives a description of the 1873 outbreak in that country, and Millous (1929), who records another outbreak involving 1,000 cases in Cochin-China in 1927. In Tonkin (Annam) the disease has been observed by Gaide (1913), in the Dutch East Indies by De Langen (1925), and in Hong Kong by Basset-Smith (1923). Farther east, Hanabusa (1917) noted it in Formosa, Goto (1923) in Pescadores, and Miki (1910) in Tokyo. The epidemic of 1922 in Japan has been reported by Kaku (1923).

THE 1934 INTERNATIONAL CONVENTION FOR MUTUAL PROTECTION AGAINST DENGUE FEVER (1935)

Public health legislation designed to control the spread of dengue fever was introduced at a congress convened for this purpose at Athens on July 25 1934. Appropriate legislation was agreed upon by the respective governments of Albania, Germany, Great Britain, Bulgaria, Egypt, Spain, France, Greece, Italy, Roumania, Turkey, Soviet Russia, and Yugoslavia, and the resolutions carried have been incorporated in a list of 9 articles. The medical measures recommended are as follows

Article 2.

When in any of the territories to which the present Convention applies, an epidemic of dengue fever shall be discovered in a port or in a district adjoining a port, the sanitary authority of the said port shall recommend captains of vessels and ships' doctors, if such are on board, immediately after leaving the port, to search out and destroy mosquitoes and their larvae in all the accessible parts of the ship, especially in the cabins, crew's quarters, store rooms, kitchens, stoke holes, water containers, and all places likely to harbor mosquitoes

The sanitary authority shall request the doctor, or failing him the captain, to take such measures, as may be necessary to insure that if cases of dengue fever occur on board the patients may be isolated under conditions such that they cannot be bitten by mosquitoes.

Article 3.

In any of the territories to which this Convention applies, all ships, coming from a port in which there is an epidemic of dengue fever and arriving in a port whose sanitary authority has reason to fear that the disease may spread owing to the presence of a large number of mosquitoes capable of transmitting it, may be subjected to the following measures —

(*a*) Boarding —The doctor, or failing him the captain, shall give a reply to the question "Are there, or have there been, on board any persons suffering from dengue fever?"

(*b*) Medical Inspection —Patients who have developed dengue fever within less than 5 days and desire to leave the ship shall be landed by day and shall be isolated on land, in accordance with the instructions of the competent sanitary authority, under conditions which shelter them from mosquito bites, until a period of 5 days has elapsed since the illness began

(*c*) Inspection of the ship in order to ascertain that there are no stegomyia on board, taking into account any measures already taken on the voyage If any stegomyia are found on board the sanitary authority may have the mosquitoes destroyed

(*d*) In exceptional cases, the sanitary authority of the port may, if he considers that circumstances render it necessary, place under surveillance those passengers who have disembarked and confine the crew on board except for purposes of duty, until a period of 8 days has elapsed since they were exposed to risk

Article 4.

When an epidemic of dengue fever has broken out in one of the territories to which the present Convention applies, and which has a land frontier bordering on another territory to which the Convention also applies, the sanitary authorities of the latter territory may, if they consider it necessary, take the following measures at the frontier

(*a*) Passengers may be placed under surveillance for a period not exceeding 8 days from the day of exposure to the infection

(*b*) Passengers suspected of having developed dengue fever within less than 5 days may be isolated according to the instructions of the sanitary authorities in conditions in which they are protected from mosquito bites until a period of 5 days has elapsed from the beginning of the illness

CLINICAL FINDINGS

The Incubation Period

The incubation of the naturally acquired infection is usually 5–8 days, but may vary from 3–15 (Ashburn and Craig, 1907 *a*, *b*, Armstrong, 1923, Cleland, 1930, Lumley, 1943)

In the case of human volunteers experimentally infected by mosquitoes, the shortest period was found to be 3 to 4 days (Ashburn and Craig, 1907 *a*, *b*), and the longest 9 to 10 days (Cleland, Bradley, and McDonald, 1919) Much the same results were observed with regard to subjects inoculated with infected blood, some of whom developed the disease in 2½ to 3 days (Ashburn and Craig, 1907 *a*, *b*), and others in 9 to 10 days (Cleland, Bradley, and McDonald, 1918, 1919). Blanc and Caminopetros (1930 *b*) found that the incubation was 3 to 7 days in the case of the experimentally induced condition.

in other areas by Adrien (1918). The Smyrna epidemic of 1889 is recorded by Credtropoulos (1890), Diamantopulos (1890), and Stamatiades *et al.* (1890). About the same time Wortabet (1887) and De Brun (1889) noted it at Beirut in Syria. The disease has been described in Baghdad, Iraq (Fleming and French, 1947). Couvy (1921) described later epidemics in Beirut and Hitti and Khairallah (1946). In Palestine Masterman (1913) gives an account of the disease; and Dive (1927) noted it at Aden in Arabia.

Europe.

Apart from the above-mentioned areas of the continent in which dengue has been observed, cases have been reported at Lisbon by Tavares (1889), and in Vienna by Eugling (1922). The latter stated that the small outbreak which occurred in the summer of 1921 in Vienna was not due to infection acquired locally, but was introduced by Macedonian immigrants.

Africa.

The disease is widely distributed throughout this continent and cases have been reported in Egypt by Sandwith (1888), Phillips (1906), and Kamal (1928), in the Sudan by Balfour (1907), Saigh (1906), and Archibald (1917), in Zanzibar by Godding (1890), in East Africa by de Sousa (1924) and McCarthy and Brent (1943); and at Accra in the Gold Coast by Corson (1921). Cases have also been reported to occur among the French naval forces stationed at Dakar (see Bideau, 1925, Perves, 1927, 1928).

India.

Dengue is found throughout the country and cases have been mentioned as occurring in Sialkot by Fooks (1908), in Calcutta by Kennedy (1912); in Meerut by Khan (1913), in Guzerat by Dalsukhram (1913), the Punjab by Farrer (1924). Other accounts are to be found in the writings of Rogers (1909), Megaw (1919), and Barrand (1928).

In Ceylon the disease is also relatively common, and cases have been recorded by Spaar (1925).

The Far East.

Dengue has an extensive distribution throughout the Far East of the globe. Cases have been reported in Burma by Pridmore (1902), and in Rangoon by Jafar and Singh (1932), in Penang by Skae (1902), in Indo-China by Vassal and Brochet (1909), in Cochin-China by Lalluyaux (1914), who gives a description of the 1873 outbreak in that country, and Millous (1929), who records another outbreak involving 1,000 cases in Cochin-China in 1927. In Tonkin (Annam) the disease has been observed by Gaide (1913), in the Dutch East Indies by De Langen (1925), and in Hong Kong by Basset-Smith (1923). Farther east, Hanabusa (1917) noted it in Formosa, Goto (1923) in Pescadores, and Miki (1910) in Tokyo. The epidemic of 1922 in Japan has been reported by Kaku (1923).

THE 1934 INTERNATIONAL CONVENTION FOR MUTUAL PROTECTION AGAINST DENGUE FEVER (1935)

Public health legislation designed to control the spread of dengue fever was introduced at a congress convened for this purpose at Athens on July 25 1934. Appropriate legislation was agreed upon by the respective governments of Albania, Germany, Great Britain, Bulgaria, Egypt, Spain, France, Greece, Italy, Roumania, Turkey, Soviet Russia, and Yugoslavia, and the resolutions carried have been incorporated in a list of 9 articles. The medical measures recommended are as follows

3rd or 4th day. Subsequently, recovery may take place in an uninterrupted manner, or else a second bout of pyrexia may occur with a further slight rise of temperature The latter is seldom as high as that of the first, and a double rise of temperature when present is referred to graphically as producing the "saddle back" type of chart (see Fig 31, and also Doerr and Russ, 1914). Antipyretics appear to

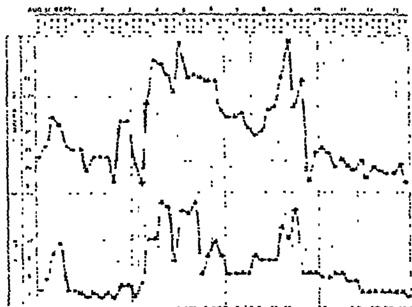

FIG. 31 Temperature and pulse chart in a case of experimentally induced dengue fever studied by Ashburn and Craig (1907)

(Reproduced from the *J infect Dis*, 1907, *4*, 440)

have little effect in combating the pyrexia (Sutton, 1904), and each occasion on which the temperature falls is accompanied by profuse sweating.

Lumley (1943) describes 5 types of temperature chart (1) continued fever, (2) saddleback type, (3) diphasic, with a normal temperature on the 3rd to 4th day, (4) monophasic type, with pyrexia for 1-4 days, (5) mild or afebrile types (see also Ross, 1948)

The Urine

albu

sugg

The Blood Picture

A well-marked leukopenia principally affecting the polymorphonuclear cells is a diagnostic feature (Balfour, 1907; Stitt, 1907, see also Ashburn and Craig, 1907 *a*, *b*, Vedder, 1907). A shift to the left of the Arneth count has been regarded by Simmons, St John, and Reynolds (1931) as most reliable (see also Hughes, 1946) Abnormal lymphocytes or monocytes with a vacuolated cytoplasm and coarse granular inclusions have been reported (Kisner and Lisansky, 1944, LeRoy and Lindberg, 1944). A marked neutropenia and lymphocytosis may persist into convalescence, along with the presence of Turk cells

The possible existence of a leukotoxin in the circulating blood during an attack of dengue fever has been suggested by Joannidès (1930).

Course of the Disease

The onset may be sudden without any indications of prodromal symptoms. Alternatively the disease may be ushered in with a feeling of chilliness, general malaise, headache, loss of appetite, and a dry throat. These are followed by the development of pains in the back and other parts of the body. A slight primary rash is sometimes seen during the first day or two of the disease, and usually affects the face, chest, neck, arms, the knees or elbows The face is often flushed, the skin is red, hot, and puffy, and the conjunctivae and mucous membranes become injected. The primary erythema, if present, may either disappear or else merge into the secondary rash which develops later in the disease. The latter commences with the second rise of fever about the 4th or 5th day of the illness, first making its appearance at the bases of the thumbs, and later extending over the hands, feet, and forearms In character it may be either morbilliform or scarlatiniform in type, and may on occasions be indistinguishable from the rash of measles It lasts for 3 to 4 days, causes itching of the skin covering the palms and soles, and *during convalescence there may be desquamation.*

The aches and pains which occur in various parts of the body during an attack of dengue fever are highly characteristic of the disease. These are, headache, backache, severe pains in joints, muscles and their tendinous insertions, and behind the eyes. Sometimes there is considerable discomfort on attempted movement of the ocular muscles and tenderness on palpation of the eyeballs. Pain in the testicles and groins may also be present. Glandular enlargements have been observed in certain epidemics only, for example Goldberger and McCoy (1907) noted them in the Brownsville (Texas) epidemic, Levy (1920) in Galveston, and Pridmore (1902) noted extensive enlargement of cervical, axillary, inguinal, and supracondylar glands in the Burma (1902) outbreak. Likewise Lane (1918) and Castellani (1917, 1938) have drawn attention to their presence. Splenic enlargement is sometimes present during pyrexia (McMullin, 1919).

Dengue in Children

At one time it was thought that children were more resistant to the disease than adults, but recent reports by various observers have shown that children ranging in age from 3 months to 15 years appear to be equally susceptible (see Choremis, 1930, and Vera, 1929) In the 1928 Athens epidemic Spyropoulos (1931) observed that among children vomiting and convulsions were common, the initial rash was well marked on the face, and the pains in joints were more frequently seen in the older children than in the younger ones. Hemorrhagic symptoms occurred less readily than in adults, and on the whole the mortality was low

Influence of Race

There appears to be no racial immunity, but some reports suggest that white persons are more susceptible than colored to dengue infection (see Christie, 1872, and Simmons, St John, and Reynolds, 1931)

The Pulse

Slowing of the pulse becomes noticeable about the 3rd day of illness and the rate becomes progressively diminished, so that during the second bout of pyrexia it may be as low as 45 beats per minute (Stitt, 1913). Hyman (1943) finds the cardiovascular signs to be due to excessive vagal or autonomic response (see also Portocalis and Flora, 1928).

The Temperature

This rises rapidly to about 102° to 103° F, and may rarely be 105° F or more, it thereafter gradually decreases during the first 2 days to reach normal about the

For a time the etiological significance of leptospira as a possible causal factor of dengue fever ground owing to the clinical re nd more especially because at from alleged cases of yellow fever. For example, Craig's (1920) judgment was greatly influenced by Noguchi's findings and he, not unreasonably, assumed that both diseases possessed a common etiological factor. Subsequent work, however, on the cause of yellow fever revealed that this disease was due to a filtrable virus, and in all probability the material supplied to Noguchi by clinicians in South America originated from unrecognized cases of infectious jaundice or Weil's disease (see p. 459). Subsequently, the leptospira theory of dengue fever was reinvestigated by Siler, Hall, and Hitchens (1925 *a*, *b*, 1926) in the Philippines, by Chandler and Rice (1923) in Texas, and by Kligler (1928) and Kligler and Aschner (1928) in Palestine, all of whom reported negative results Thus, the Palestine workers could not detect leptospira in the blood of 9 cases of dengue, either by cultural or direct microscopical methods of examination. They, moreover, were unable to find leptospira in several thousands of insects which had been caught in infected houses. Finally, it was proved that a leptospira is unable to survive for more than 16 hours in *Stegomyia* and no longer than 48 hours in *Phlebotomus papatasii*. Results such as these offered conclusive evidence in favor of the fact that dengue fever is not a spirochetal infection. Similar observations regarding the possible leptospira theory of sandfly fever were carried out simultaneously by Kligler and Aschner (1928), and these are described in Ch XLIV.

EXPERIMENTAL WORK ON THE VIRUS

Human Transmission and Filtrability

Modern research on the virus agent of dengue fever originates from the work of Ashburn and Craig (1907 *a*, *b*) who studied the condition at Fort William McKinley, Rizal, in the Philippine Islands during an epidemic that affected over 800 soldiers One hundred and twenty eight cases were transferred to the hospital at Manila (in which city the disease was absent at the time) and experimental work on human volunteers was performed there. First, the blood of numerous patients was examined for the possible presence of organisms by direct microscopy and cultural methods, but the results were negative throughout. These two workers then showed that, when blood was removed from cases of dengue fever on the 3rd or 4th day of the illness and inoculated into 11 volunteers, it reproduced dengue in 7 of them. The longest incubation period was found to be 7 days, the shortest 2½, and the average 4 days

Experiments were next conducted in order to find out whether the infective agent was filtrable Accordingly, blood was obtained from patients, rapidly defibrinated, diluted in saline, passed through a Lilliput diatomaceous earth filter candle (which was c
intravenously with
cal attack of dengue
ceptbile individual is
mura, 1917) Further researches of a similar character were performed in Australia by Cleland, Bradley, and McDonald (1919) who passed the virus through the Pasteur-Chamberland F filter They, moreover, discovered that it was uniformly distributed throughout whole blood, being present in filtrates of serum or citrated plasma Likewise, well-washed corpuscles proved to be infective. The virus was

Cerebrospinal Fluid

Manoussakis (1928) demonstrated that this fluid contains the virus and is infective. There may be a slight increase in cells and albumin (LeGac and Servant, 1939).

COMPLICATIONS

Complete recovery is usual, but on rare occasions complications supervene.

Hemorrhages. In severe cases these may occur from the stomach, nose, genitourinary tract, kidneys, and bladder. Subcutaneous skin hemorrhages are also prone to occur, and Rumpel Leede's and Marwitz-Deriecke's tests become positive (Georgopoulos, 1928).

Eye lesions may take the form of paralysis of various muscles, or iritis and sometimes even keratitis. Richardson (1927) reports 6 cases of keratitis which he observed during convalescence in the Jacksonville epidemic. Dengue fever has also been known to precipitate an attack of acute glaucoma in an individual.

The central nervous system Dengue fever may be accompanied by signs and symptoms of disease referable to the nervous system. Perhaps the commonest of these take the form of attacks of mental depression during illness, which may occasionally be prolonged into convalescence Severer involvement of the central nervous system, e g. with paralysis, may occur (Tsiminakis, 1930, Avaritsiotis, 1930, Kaplan and Lindgren, 1945). It seems possible that a true dengue encephalitis may occur (Lumley, 1943)

Instances in which *orchitis* or *oophoritis* have followed an attack of dengue have been noted (Nicolas, 1927, Weyrauch and Gass, 1946). *Dengue fever as a pyrotherapeutic remedy* has been recommended by Pamboukis (1930) for the treatment of certain nervous diseases such as parkinsonism following encephalitis, epilepsy, and general paralysis of the insane. *Surgical complications* arising during the course of dengue infection have been described by Kondoleon and Joannidès (1930).

POSTMORTEM FINDINGS

The mortality due to dengue is exceedingly low and, for example, McCallum and Dwyer (1927) estimated that it was about 0 03 per cent. during the Queensland epidemic In consequence of the small death rate, little is known regarding the morbid anatomical or histological features of the severest cases Photakis (1929) reports that in autopsies performed by him on fatal cases, he found enlargement of the liver and degeneration of the myocardium The kidneys and suprarenal glands appeared to be normal No renal lesions could be found to account for hematuria which occurred prior to death in certain cases

ETIOLOGY

In earlier studies numerous workers at different times have claimed to have discovered the specific etiological agent of the disease. Thus, various types of bacterial and protozoal parasites have been found in the blood of patients by McLaughlin (1886), Eberle (1904), Reiche (1906), Nagib (1910), and Graham (1903) Holt (1923) observed a pleomorphic bacterium in human blood as well as in that of "infected" animals, and Harris and Duval (1924) isolated globoid bodies in cultures made from patients McMullin (1919) suggested that the disease was an allergic manifestation brought about by repeated introductions of mosquito protein

The Spirochete Theory

Spirochetes were observed in the sputa of certain human cases by Allen (1908) They were also isolated from blood by many investigators such as Couvy (1921), working at Beirut in Syria, and also by Vervoort (1922) and van der Velde (1923) in the Dutch East Indies

quinine. The virus cannot be absorbed from serum by treatment with calcium carbonate or tapioca (see Blanc and Caminopetros, 1930 *b*, *c*)

Animal Inoculation Experiments

There is no evidence that either domestic [illegible] in nature (Cleland, 1930). Attempts to infe[illegible] and rabbits proved negative (Simmons, St. [illegible] Schlesinger (1945), however, adapted virus to mice by the cerebral route, and produced a modified attack in man with passage virus.

Only partial success has been achieved in the case of larger animals such as guinea-pigs and monkeys Inoculation of the latter causes a mild febrile reaction which may sometimes be accompanied by leukopenia. During this period of transient illness the virus can often be demonstrated in the animal by inoculating a human volunteer with a small quantity of its blood. Animal infection of this character has been referred to by Nicolle (1928) as "inapparent" infection because, although the virus survives and multiplies for a time in the animal, it fails to establish itself in it Thus Blanc, Caminopetros, and Manoussakis (1928), showed that 5 days after inoculation of a guinea-pig with infected human blood, the animal's blood proved pathogenic to a human volunteer. Likewise Findlay (1932) found that the same held true in the case of a rhesus monkey whose blood contained the virus 7 days after it had been infected, although the animal only showed a slight leukopenia without obvious signs of illness. Blanc, Caminopetros, Dumas, and Saenz (1929) made a similar observation, when they experimented with the following monkeys *Cynomolgus sinicus*, *C. fascicularis*, *Cercopithecus callitrichus*, *Cercocebus aethiopis*, and *Papio babuin*. They found that the blood of the animals first became infective for humans 5 to 8 days after inoculation, but ceased to be so after the 12th day. Attempts to transmit dengue virus by passage from one monkey to another were unsuccessful. Simmons, St John, and Reynolds (1931) found that the Japanese monkey, *M fuscatus*, was also susceptible and exhibited a transient febrile illness following inoculation Simmons (1931) obtained positive results with *M. philippinensis* as well as in *C fascicularis*, *C callitrichus*, and *M. fuscatus* monkeys He found that the animals suffered from latent dengue infection and, although their blood was noninfective for humans 24 hours after injection, it acquired infectivity from the 5th to the 8th day. On the 12th day, however, the virus disappeared from their blood, and thereafter the monkeys became solidly immune to reinfection for a period of 15 days In view of the ability of monkeys to harbor dengue virus in their blood stream, Simmons (1931) has suggested that lower animals may act as reservoirs of infection for dissemination of the disease in certain areas

IMMUNITY REACTIONS IN MAN

A number of workers has found that active immunity persists for a year or more on recovery from infection (e g, Blanc and Caminopetros, 1929 *b*, Sharp and Hollar, 1935) Lumley (1943) concludes that one attack tends to give a short-lived immunity, but that subsequent attacks tend to be milder, residents in endemic areas develop, by constant exposure, some resistance to attack

Attempts at active immunization have been made. Simmons, St. John, and Reynolds (1931) had negative results with vaccines prepared from infected mosquitoes and human blood St John and Holt (1931) used infected monkey tissue. Blanc and Caminopetros (1930 *b*) achieved some success with bile-treated human serum More success may follow the use of mouse-brain virus (Sabin and Schlesinger, 1945)

L_7 and L_{11} bougies, and Kligler and Aschner (1928) filtered it through the Berkefeld N candle. Simmons, St. John, and Reynolds (1931) showed that it could pass through the Berkefeld V filter.

The infectivity of blood from human volunteers has been confirmed by subsequent investigators. The virus will survive for some time and specimens can be sent to distant laboratories (Philip, 1946). Lumley (1943) summarizes the position by stating that virus is present in the blood as a rule from 1 day before to 5 days after the onset of illness.

Morphology

Since the virus is very small in size, it lies beyond the range of visibility of the ordinary microscope, and consequently it has not yet been possible to demonstrate it in stained preparations Sellards and Siler (1928) observed, however, that large numbers of rickettsia-like organisms could be found in dengue-infected *Aedes* mosquitoes, in microscopic preparations stained by Giemsa or Mallory's eosin methylene blue technique. Such rickettsiae were absent from control mosquitoes, but in these there was present instead a protozoan parasite, *Lankesteria culicis*, due to which a certain amount of confusion arose. The results of the investigation are thus inconclusive. Coles (1937) has described minute granules in infected blood which he has called *Maculae dengui*

Cultivation

Shortt, Rao, and Swaminath (1936) inoculated developing chicken embryos (see Ch. XIII) with the blood of dengue fever cases derived from patients on the first day of their illness. Eggs were inoculated with either plasma or serum from 19 typical cases of dengue fever, and of these 15 produced lesions on the surface of the chorio-allantoic membrane In appearance these were similar to changes reported in their experiments on sandfly fever (see p. 523) but with certain differences. For example, the lesion of dengue virus on the membrane was considerably thicker than that caused by sandfly fever virus, and whereas on section the edges of the former were approximately parallel to each other, the margins of the latter tended to be curved and bulging in their contour. Microscopically also certain differences have been detected The distribution of inclusion material present in dengue virus lesions of the membrane appeared to be identical with those reported in the case of sandfly fever virus.

Reaction to Physical and Chemical Agents

Cold The virus retains its infectivity in human blood if stored in a refrigerator at 0° C. for about 2 months (Blanc, Caminopetros, and Manoussakis, 1928).

Heat. Manoussakis (1928) found that the thermal death point of the virus was 50° C. for half an hour, and that exposure to bright *sunlight* for 30 minutes failed to inactivate it.

Desiccation The infectivity of human serum can be preserved for long periods of time by drying it Such material has been employed by Findlay (1932) for the inoculation of human volunteers in London Simmons, St John, and Reynolds, (1931) found that the virus survived for a longer time in living than in dead *Aedes,* in which it only existed for about 4 days at 18° C.

X-rays. The action of these rays on *Aedes* infected with dengue virus has been investigated by Holt, Fleming, and Kintner (1931), who found that exposure of the insects to erythema doses neither killed the virus, nor modified the course of the disease in human volunteers who were permitted to be bitten by the mosquitoes after these had been treated with the rays *Ultraviolet light* likewise failed to exert any effect on the virus

Chemicals The virus resists a 1 in 800 dilution of formalin for 5 hours, 0 5 per cent. cholesterin for 15 minutes, 1 in 500 neutral red for 7 hours, 95 per cent al-

Although resistance following the disease may be lasting, the serum of an immune subject appears to contain no virus neutralizing antibodies Many workers have drawn attention to this point. For example, Blanc and Caminopetros (1929 *c*) showed that neither whole blood nor serum derived from convalescent cases possessed any protective properties. Holt, Fleming, and Kintner (1931) also obtained negative results with convalescent sera. Partial success has been obtained with complement fixation tests using ground-up infected mosquitoes as antigen

Efforts to prepare therapeutic or prophylactic antisera have failed, Blanc, Caminopetros, and Giroud (1929) found that antisera prepared in rabbits were useless. Yellow fever antiserum and anti-hog cholera serum did not exert a beneficial effect on cases of dengue fever (see also Dinger and Snijders, 1931).

RELATIONSHIP TO OTHER VIRUSES

Recently, numerous tests have been performed in order to elucidate whether dengue virus possesses any properties in common with yellow fever virus on the one hand and Rift Valley fever virus on the other. Dinger and Snijders (1931) made the important observation that monkeys which had recovered from an attack of dengue fever were subsequently resistant to infection with yellow fever virus But although this was the case, the sera of dengue-immune monkeys failed to neutralize yellow fever virus. Hanson (1936) mentions an interesting case in which an individual who had suffered from dengue fever developed an attack of yellow fever a year later. Blanc, Caminopetros, and Giroud (1929) found that yellow fever antiserum did not neutralize dengue virus, and Sharp and Hollar (1935) reported that human serum from a case of dengue fever gave a negative mouse protection test against yellow fever virus. In cases where doubt exists, the clinical differential diagnosis between dengue and yellow fever may thus be established by application of the mouse protection test (see p 507) With regard to the possible relationship of dengue virus to Rift Valley fever virus, Findlay (1932) reported that monkeys which had been immunized against dengue virus were not resistant to Rift Valley fever virus, and vice versa This subject is discussed more fully in Ch. XXXVI

Challenge experiments in human volunteers did not elicit any relationship between dengue and Colorado tick fever (Florio *et al*, 1946, Pollard *et al*, 1946, Koprowski and Cox, 1947), or Bullis fever (Livesay *et al*, 1946)

FORT BRAGG (PRETIBIAL) FEVER

In the summer of 1942, a dengue-like illness attacked troops at Fort Bragg, North Carolina, there were similar outbreaks in the summer of 1943 and 1944 Tatlock (1947) describes the clinical features of a case as follows. sudden onset of headache, with fever, and generalized aches, 5 days after onset he developed a maculopapular eruption over the pretibial areas, the fever lasted for 5 days, and the patient made a rapid recovery The causal agent was found in the blood 48 hours before and after the onset of fever Tatlock isolated an agent, presumably a virus, by inoculating guinea-pigs with blood from a human case The agent induced fever in guinea-pigs and rabbits, and killed hamsters The agent was passed in animals, or fertile eggs (by the intravenous route), and after prolonged passage infected human volunteers Some of these developed fever for 1–3 days, and showed the clinical picture of Fort Bragg fever

The causal agent appeared unrelated to LCM, Q fever, Rocky Mountain spotted fever, sandfly and dengue fevers

YELLOW FEVER—HISTORICAL ACCOUNT

Place of Origin

... of yellow fever is to be ... has endeavored to eluci- ... epidemiological records. ... in West Africa and was introduced into America by sailing vessels and their personnel The insect vector *Aedes aegypti* was in all probability also imported into the New World at the same time. In his efforts to trace the chronological sequence of the earliest recorded outbreaks of yellow fever, Carter's researches have been hampered by the fact that, whereas the Spanish-American literature was plentiful and complete, no native documents existed relating to the incidence of the disease in West Africa

According to Carter, the first reliable account of yellow fever in America was given in 1648, but Hirsch (1883) mentions that Du Tertre of Guadeloupe referred to it in the year 1635. In Africa it was not described until 1778, when Schotte (1782) drew attention to its presence in Senegal territory. Although yellow fever was recorded in America about 130 years prior to its recognition in Africa, there is evidence to suggest that it originated in Africa, and then spread westward. For example, when yellow fever was noticed in the Yucatan in 1648, it was clearly recognized in that land as a new and hitherto unidentified disease, but Schotte's account of it in Senegal in 1778 hints that the malady was merely a recrudescence of a similar condition encountered previously.

America.

According to Carter, yellow fever was not present in America either at the time of the landing of Columbus or for many years thereafter. Following its appearance in the Yucatan in 1648, Carlos Juan Finlay (1912) reported that it occurred in 1649 in Cuba. Here the disease affected the fleet of Don Juan Pujadas as it lay at anchor off Havana. After 1665, yellow fever disappeared from Cuba until 1762, when it was reintroduced by prisoners sent from Vera Cruz to assist in rebuilding Cabanas after its siege and capture by Pocock and Albemarle. Subsequently the disease remained endemic in the island up to 1901, when Gorgas is reported to have instituted antimosquito measures and thereby eradicated it. Carter points out that Cuba was the first place from which yellow fever was abolished by the introduction of mosquito control. In 1640 Pernambuco was affected, in 1665 the island of St Lucia was invaded, and by 1658 the infection had spread throughout Brazil Thereafter it was spread through Mexico and Central America by the movements of troops engaged in wars waged at the time.

Colombia.

In Colombia, the emerald mines at Muzo were first attacked in 1885, allegedly owing to the introduction of infection by troops from Honda The Muzo mines have long remained a permanent endemic source of infection and Gorgas (1917) investigated epidemics in 1916 and 1923 without discovering cases of yellow fever or *Aedes aegypti* all of which, in the light of current knowledge, are suggestive of jungle yellow fever. Cases occurred at Bucaramanga in 1810 and 1923, Buenaventura on the Pacific coast in 1920, and after a period of 6 years of freedom from infection in Colombia, the town of Socorro Santander suffered in 1929 (Smith, Bevier, and Bugher, 1943)

was conveyed from there into Granada in 1793 by the ship Hankey (see Chisholm, 1801).

THE PART PLAYED BY SAILING VESSELS IN THE SPREAD OF YELLOW FEVER

Ships have long been recognized as an agency by which the disease has been disseminated, and in 1883 Hirsch categorically stated that "yellow fever goes practically no farther than the traffic by sea, the disease for the most part finds its limits where that medium of communication ends" The evidence goes to prove that the windjammer of bygone days provided more favorable surroundings for the transit of infected mosquitoes than does the modern liner. It was repeatedly proved that *Aedes* could live for months and even breed in the humid, warm, ill-ventilated compartments of the old-time sailing vessels. In the case of the modern ocean liner, with the exception of rain water in lifeboats, there are few breeding grounds for mosquitoes on board, since there are no uncovered water tanks and the introduction of forced-draught ventilation tends to drive the insects out of the ship With regard to sailing vessels, the conditions appear to have been particularly bad on the Finnish and Swedish craft, and early writers such as Lallemant (1857) and others were loud in their condemnation of the filthy state of these boats Many bluntly attributed the disease to the insanitary living accommodation provided on the vessels, and Hirsch made the observation that yellow fever was chiefly to be found among the poorer classes who dwelt in dirty surroundings, amid the squalor and poverty-stricken quarters of human dockland habitations These early accounts make fascinating reading, for even although they do not blame insects as being possible vectors of infection, they are nevertheless interesting, since the experiences related are in accordance with our modern knowledge concerning the rôles of *Aedes aegypti* in the propagation of maritime and urban yellow fever For example, it has been noticed that the disease was sometimes limited to the crew of a ship, or that it was occasionally confined to one side of the vessel, or else to a single cabin. The presence of a high wind or cold weather experienced during the time of an epidemic were also said to modify its course. Indeed, it may be said that the early literature contains many shrewd observations which bear remarkable testimony to the accuracy of the facts as reported by pioneer workers

So often has yellow fever been transmitted by ship, that it has been popularly asserted that it has been sent backwards and forwards like a shuttlecock between Pernambuco and the Slave Coast of Africa. Under the circumstances, it is worth considering in detail the precise mechanism by which its spread is effected by sea We would again remind the reader, however, that although yellow fever is conveyed by ship, either through the transference of infected mosquitoes or human patients, a combination of factors is needed before the disease can establish itself permanently in any land As mentioned previously, 3 factors are essential for survival of the disease, namely, a human case of yellow fever, the insect vector *Aedes aegypti*, and last, but most important of all, the existence of susceptible individuals The theoretical possibilities of the spread of infection may be enumerated as follows (1) If an unrecognized case of the disease (during its incubation period) were to be landed at a port at which *A aegypti* were present together with a non-immune human population, a severe epidemic might ensue Should, however, *A aegypti* be absent, then it can be assumed that there is no likelihood of further human cases occurring in the district (2) The transportation of infected *Aedes* from one port to another forms the major problem of these two The presence of infected mosquitoes on a vessel may spread the condition in a variety of different ways Either the insects may infect susceptible sailors on board, or else those who come aboard the ship at its port of destination. If the temperature of the latter is favorable, the mosquitoes may leave the vessel and attempt to form a local colony

The Atlantic Islands.

The name of the island of St. Thomas, which lies about 200 miles off the coast of West Africa in the Cape Verde group of islands, appears to have figured prominently in the literature. Although today these islands are healthy places, free from yellow fever (see Colonial Office Report, 1920), at one time they seem to have been an endemic center of the disease, and there are numerous reports to the effect that St. Thomas was a notoriously unsalubrious spot. Sir Richard Hawkins (1622), [illegible] South Seas, alluded to the Cape Verde [illegible] are held to be scituate in one of the [illegible] therefore it is wisdome to shunne the sight of them, how much more to make abode in them. . . . In two times that I have been in them either cost us the one halfe of our people with Fevers and Fluxes of sundry kinds . . . and in one of them it cost me six monthes sicknesse with no small hazard of life." In 1585 Drake and Carleill captured the island, and spent 10 days on it, but after returning to their ships some days later many of their sailors developed a fever, as a result of which 300 of them died at sea. From Bigges's (1652) description of the signs and symptoms seen and complained of by Drake's sailors, Carter has identified the condition as being yellow fever. Other European expeditions to the island likewise suffered from the disease, which was prevalent during the time of the Brazilian wars that were fought between the Portuguese and the Dutch in 1624. Thus, both Menezes, who visited the island in 1624, and Mascarhenas, in 1638, suffered loss from its ravages.

Between the years 1581 and 1640, St Thomas was employed as a regular port of call for Portuguese and Spanish merchantmen trading between Europe and the New World, as well as for ships of other nationalities. The island was, moreover, the center of the slave trade and in regular communication with the African coast. St. Thomas was first colonized in 1485 and it is highly probable that, after yellow fever was imported into it from the mainland, it remained a permanent endemic focus for dissemination of the disease to the Western hemisphere. The forgoing facts pertaining to this island are not merely of historical interest but of great epidemiological significance, in so far as they clearly illustrate the requisite factors essential for the establishment of an infected area. Here the insect vector *Aedes aegypti* was present (either being found on the island before its colonization or else introduced into it by ships from the mainland), human cases of the disease were plentiful and, most essential of all, the constant influx of highly susceptible European sailors helped to swell the proportion of infected *Aedes* mosquitoes. A combination of favorable circumstances for the perpetuation and maintenance of infection thus appears to have existed on this island

The Canary islanders suffered repeatedly, and epidemics were reported from 1701 to 1888. From all accounts, it seems logical to conclude that, in early times, certain of the Atlantic islands which were used as ports of call by ships played a conspicuous part in the dissemination of yellow fever

Africa.

Lind (1792), an authority of his day on tropical diseases, described a condition not unlike yellow fever among sailors stationed on the sloop *Merlin* as it lay at anchor in the Gambia River in August, 1768. He stated that only men who had gone inland to fell wood in the forests contracted the disease, whereas those who had remained on board were unaffected In the following year, in 1769, the same fever was again observed by Lind to attack sailors attached to the *Weasel* and the *Hound* when lying in the same waters

Schotte (1782) studied the disease from 1775 to 1778 at St Louis de Senegal and presented a summary of his findings in the text of a report to the Royal Society, titled *Synochus Atrabiliosa* Yellow fever was next reported in Boullam and

ETIOLOGY

The progress made during recent years in the etiology, diagnosis, and prophylaxis of yellow fever may well be classed among the greatest achievements of modern medicine. During the first 2½ centuries following its appearance, man had been powerless to combat its ravages, as the mode of spread and origin were completely unknown. It was not, however, until 1881 that Carlos Finlay (1881, 1904, 1912) of Havana first suggested that infection was spread by a mosquito, and later, in 1900, that the classical researches of Reed and Carroll (1902) definitely established it as a virus disease which was transmitted by *Aedes aegypti*.

In these early times, before prophylactic vaccination was known, research work on yellow fever was attended with great personal risk to investigators, as a result of which many distinguished medical men lost their lives, one was Hideyo Noguchi, the celebrated Japanese bacteriologist, whose romantic life story has been narrated by Eckstein (1931).

Noguchi deserves special mention, as, in 1925, when working in South America, he isolated *leptospira* from cases of jaundice believed to have been cases of yellow fever by the local clinicians, but which in reality were Weil's disease Noguchi

he had been misled by cliniciar-
diagnosed cases in America. U
since before he could publish
victim to yellow fever and di
shared his unhappy lot were
Paul A. Lewis, and Theodor
posterity in the history of bacteriology. No reference to the subject of yellow fever would ever be complete without reference to the prominent part played by members of the International Health Division of the Rockefeller Institute, and in the following pages are included some of their many accomplishments

MODERN ANTIMOSQUITO MEASURES IN THE PREVENTION OF EPIDEMIC YELLOW FEVER

For effective mosquito control Public Health legislation is required, and much of the success in any district depends not only on the willingness of the inhabitants but also on the nature of the laws Thus, the rules should be drafted by ex-
ites of mosqui-
with sufficient
the town and,
if necessary, to force uncooperative owners of premises to carry out such structural alterations to their buildings, as may be deemed necessary to eliminate the breeding places of mosquitoes The value of antimosquito laws may be enhanced by the incorporation of clauses making the mouse protection test and viscerotome postmortem examination compulsory under circumstances where the cause of death is unknown One of the most comprehensive series of antimosquito regulations devised, and one well worth reading, is to be found in the Decree 21,434 of May 23, 1932, Approving the Regulations of the Services for the Prevention of Yellow Fever in Brazil. Without exception, in every country in which active antimosquito laws have been applied, there has been a corresponding decline in the incidence of epidemic yellow fever (Low, 1920)

on shore. This actually occurred in France at St. Nazaire in 1861, when the ship *Arequippa*, which called at the port, became infected in this way by mosquitoes from a neighboring vessel. On the other hand, if the shore temperature conditions are uninviting, the *Aedes* may remain in the vicinity of the ship and bite workmen occupied on the quay sides and docks lying within their range of flight Thus the outbreaks which occurred in Halifax in 1842 and 1861, and in Portland, Maine, in 1801, were ascribed to this cause (Carter, 1931). Similar localized epidemics occurred at Swansea in Great Britain in 1864 and 1865 (Buchanan, 1866), and at Southampton in 1866 and 1867 (Wiblin, 1866–7), when laborers and customs officials who had come into contact with infected ships contracted the disease.

During the years 1700 to 1878, according to Hirsch (1883), localized outbreaks and sporadic cases were reported from the following European localities.

Cadiz	1700, 1730–1, 1733, 1764, 1780, 1800, 1804, 1810	Andalusia	1819–21
Lisbon	1723	Granada	1819–21
Oporto	1851, 1856 (120 cases)	Tortosa	1821
Malaga	1741, 1803, 1804	Barcelona	1821, 1870
Madrid	1878	Brest	1802, 1839, 1856
Cartagena	1810	St Nazaire	1861
Gibraltar	1810, 1828	Swansea	1843, 1851, 1864, 1865
		Southampton	1852, 1866, 1867

There is another possibility, to which Carter (1931) has drawn attention, that illustrates how effectively infected mosquitoes can be locked up in ship compartments, and start disease only at the end of a long voyage. He cites several instances in which this happened. For example, in 1890 when the *Curlew* arrived at Ship Island Quarantine Station after a 58 days' voyage from Rio, although there had been no illnesses during the voyage, one of the seamen developed yellow fever 4 days after he had entered one of the ship's hatches. On the second occasion, when the British bark *Chippewa*, which had arrived from Rio after spending 68 days at sea without any history of illness on board, reached Ship Island, 2 cases of yellow fever developed on board

The foregoing experiences show how easily infected mosquitoes can be transported at sea They furthermore reveal that the apparent absence of illness on board a vessel by no means implies that it is free from disease, as the infected insects aboard the vessel may not have had access to the crew during the voyage, or else if they did so, the men may have been immune to infection

Before leaving this topic, we should like to refer to the Madrid outbreak of 1878, which presented certain unusual features and illustrated how contaminated baggage could convey the disease by railroad transport far into a country. The associated circumstances were as follows In 1878 a regiment of soldiers, who had previously been in excellent health, returned to Santander from Cuba About one-half of the men proceeded directly from Santander to Madrid by railway train, conveying with them their unopened kit, which was unpacked and cleaned at Madrid for the first time since they had left Cuba Soon afterwards cases of yellow fever developed among members of the civil population, whereas the troops continued to remain unaffected Guichet (see Hirsch, 1883), who described this epidemic, stated that "Yellow fever at Madrid was due to the importation of morbid germs among the clothes and baggage of men in good health returning from Cuba" Although the existence of mosquitoes was never alluded to in this account, the essential facts were so graphically narrated, that the cause of the epidemic could have been due to none other than to infected *Aedes* present in the troops' baggage

The fact that only the civilians suffered is also easily explained, as the troops were probably immune to infection by previous exposure to attack when serving abroad, whereas the inhabitants of Madrid were unprotected, and therefore highly susceptible to infection.

there has not been a single case on record where infected mosquitoes or patients have been transported by air.

Admittedly the airplane may be a potential source of danger, but simultaneously the boundaries of human yellow fever have been pushed backwards and the advent of DDT ... ledge of the ... minimized ... fully aware ... l action of DDT on the upholstery of airplanes has been studied by Madden, Lindquist, and Knipling (1946) who concluded that DDT was a useful adjuvant to normal spraying which it should reinforce but not replace.

INDIA AND THE DANGER OF YELLOW FEVER

The late British Government of India was conscious of the danger of the entry of infected *Aedes* or human cases of yellow fever through the airport of Karachi

Sprawson (1936) emphasized the point that in India there existed a large population of nonimmunes to yellow fever, coupled with an abundance of the insect vector *A. aegypti* in the country. For example, in Calcutta alone the index of *A. aegypti* was estimated to be 12 6 per cent, by the researches of Chowdhury and Ganguli (1937) who collected 2,624 mosquitoes from 20,825 dwelling houses in the city. An Indian strain of *Aedes aegypti* has been shown by Hindle (1929) to be capable of transmitting yellow fever. There is, therefore, no justification for any supposition that the absence of yellow fever in India is due to a biologically different species of *Aedes aegypti* in that country which is incapable of functioning as a vector Another potential carrier of infection is *Stegomyia vittata* (*sugens*) which is widely distributed throughout Ethiopia, Aden, the surrounding hinterland, and India. If yellow fever were introduced into India, the consequences would be too terrible to imagine, for, in addition to the factors already mentioned, it must be remembered that the Indian *M rhesus* monkey is highly susceptible to the disease and would constitute another source of danger To prevent the introduction of the disease, Sprawson proposed at the Pan-African conference that the following ...

tained by appropriate methods, (3) that the personnel of all aircraft be actively immunized against yellow fever (see p 503).

As yet, there is no record in the literature of yellow fever being transported by air to any new locality. This has doubtless been due to the efficiency with which the authorities concerned have tackled the problem, and if recommendations such as those suggested above are rigorously enforced, there is no reason to fear that infected mosquitoes will be conveyed by air. The transport of unrecognized human cases of yellow fever (for example, during the incubation period) is, however, a more dangerous and less controllable factor To take a hypothetical case, a susceptible individual in good health may be bitten by an infected *Aedes* on the morning of his departure by airplane from West Africa. A few hours later the person may arrive at Karachi, pass through the airport, and later develop the disease elsewhere in the country. Admittedly this is an extreme example, but it is nevertheless a contingency worth entertaining, if it is remembered that to-day it is possible to travel from England to Australia in less than a week Theoretically, a period of 7 days' quarantine for all air passengers would be the ideal means of controlling infection such as that alluded to above, but unfortunately the introduction of quarantine would defeat the advantages gained from speedy air travel!

The transport of unrecognized human cases of endemic yellow fever is another problem which has some bearing on this subject Hoffmann (1937) states that

Dichloro-diphenyl-trichlorethane (DDT) $(ClC_6H_4)_2$ $CHCCl_3$

The insecticidal efficacy of DDT is too well known to warrant further description. Webster (1946) recommends that mosquito breeding marshes should be sprayed with a solution of DDT 20 per cent, triton 20 per cent. and xylene 60 per cent., diluted with water to form a 5 per cent. final concentration of DDT in aqueous emulsion. One to 2 quarts per acre suffices. A dilution of one part per million prevents breeding of mosquito larvae for several weeks and a concentration of 25 mgms per sq. ft., 100 days after application kills adult mosquitoes in 4 hours. At a concentration of 50 mgms per sq ft. after a lapse of 308 days mosquitoes are killed in 24 hours.

Although DDT displays great powers in persistence, its immediate lethal effect (in low concentration) is small and to overcome this defect DDT is combined with pyrethrines such as in the very successful American aerosol bomb. (See review by Baillie, 1946.)

According to Elmendorf, Marucci, Griffin, Myer and Ryan (1946), tests on 18 mesh per inch wire screens painted with 200 mgs. DDT per square foot, showed that 30 minutes after 4 contact exposures, some 61.1 per cent. *Aedes aegypti* failed to bite. Domestic species of mosquitoes in the hunt for food would presumably rest on the walls of houses prior to biting the inhabitants. There is still opportunity for further research on the choice of solvents, crystallization effects, and the action of weathering.

DDT promises to be an important weapon in the control of *Aedes aegypti* wherever it may occur. For instance, at Georgetown, British Guiana, in spite of heavy rainfall in April–June the application of DDT successfully reduced the *Aedes aegypti* house index (for adults, pupae, and larvae) from 2.19 per cent. at the end of 1945 to 0.32 per cent. at the end of June, 1946. A single spraying of the walls of houses with 5 per cent. DDT in kerosene remained insecticidal for 10 months (de Caires, 1946).

STEAMSHIPS AND THE SPREAD OF YELLOW FEVER

The modern ocean liner is less likely to convey yellow fever from one port to another than the old-time sailing vessel because *Aedes aegypti* is a comparatively delicate insect which avoids air currents and temperatures below 65° F. (see Low, 1920). Furthermore, as modern vessels are equipped with steam water condensers there are no accessible water barrels or similar storage receptacles in which mosquitoes can breed. It seems improbable that steamers can convey infection to any extent, and at the Paris International Sanitary Conference (1911–12) it was emphatically stated that "there was not a single instance on record where yellow fever had been conveyed overseas after a long voyage, on a steam vessel to another country, unless an actual human case or cases of the disease had previously occurred during the voyage." Thus the chances of yellow fever being transmitted from South or Central America, across the Pacific over a distance of 11,000 miles, to Calcutta in India, are remote.

AIRCRAFT AND SPREAD OF YELLOW FEVER

According to Findlay (1946), the present organizations for the prevention of yellow fever and other diseases by aircraft are unsatisfactory. Mosquitoes have been proved to survive journeys of 9,000 miles at heights of 10,000 to 12,000 feet. Findlay believes that the sanitary conditions of airfields, aircraft, air passengers, crews, and ground staffs may be inadequately supervised and that yellow fever immunization certificates may be an ineffective check through evasion, forgery, or faulty preparation, dilution, and administration of vaccine. Notwithstanding the many opportunities for wilful evasion or unintentional neglect of official instructions, it is perhaps true to state that throughout the war years and postwar period,

permitting of its development, inoculation of such personnel is recommended. (6) That all persons inoculated in compliance with the provisions of paragraphs (4) and (5) of this Article shall be furnished with and carry an Inoculation Certificate signed by the officer carrying out the inoculation This certificate shall conform to the International Form of Certificate of Inoculation against yellow fever annexed hereto (7) That persons in possession of a valid antiyellow fever inoculation certificate shall not for the purpose of the control of yellow fever be subjected to quarantine restrictions. (8) That in place of a valid antiyellow fever inoculation certificate, a certificate that the bearer has recovered from an attack of yellow fever and that his blood contains immune bodies against yellow fever, as proved by

risk of contracting yellow fever during the period of his stay in an endemic yellow fever area. (10) That UNRRA shall lay down standards with which yellow fever vaccine shall conform. (11) That they will make arrangements to test at frequent intervals the activity of the yellow fever immunizing vaccine in use in order to insure that its immunizing properties are satisfactory, and for this purpose agree that UNRRA in consu

Western Hemisphere,

time to time institutes

Article 37 require

UNRRA

Article 38 deals with provisions concerning regions in which yellow fever is discovered or exists in endemic form. Salient features are that aerodromes be situated in areas where water supplies and human dwelling quarters can be made

are that all aircraft should be disinsected, travelers not in possession of the official yellow fever inoculation certificate are to be isolated in screened quarters for 6 days

Article 49 deals with territories or regions where conditions do not permit of yellow fever developing Aircraft may land on any authorized aerodrome, the plane be disinsected and the occupants inspected medically.

Ships

The following are 2 of the regulations laid down by the International Sanitary Convention (1926) amended 1944

"Article 35 A ship shall be regarded as *infected* if there is a case of yellow fever on board, or if there was one at the time of departure or during the voyage. A ship shall be regarded as *suspected* if it had no case of yellow fever but arrives after a voyage of less than six days from an infected port or from an uninfected port in close relation with endemic centers of yellow fever, or if when it arrives having been more than six days out, there is reason to believe that it may carry winged *Stegomyia* (*Aedes aegypti*) from the said port. A ship shall be regarded as *healthy*, notwithstanding its having come from a yellow fever infected port, if, having had no case of yellow fever on board and arriving after a voyage of more than six days, there is no reason to believe that it carries winged *Stegomyia*, or when it proves to the satisfaction of the sanitary authority of the port of arrival (*a*) that during its stay in the port of departure it kept at a distance of at least 400 meters from the inhabited land and at such a distance from the pontoons as to make the access of *Stegomyia* improbable, (*b*) or that at the time of departure it was subjected to effective fumigation in order to destroy mosquitoes

endemic yellow fever in man is associated with slight, noncharacteristic manifestations of illness which may sometimes be unrecognizable clinically. Such cases in the past, he says, have escaped detection, and are to-day being found as the result of routine viscerotome examinations of all cadavers in different countries If this is so, then it should be a comparatively easy matter for an individual suffering mild endemic yellow fever to be transported by air to a locality where the disease does not occur. Subsequently, if the latter country contains the insect vector as well as nonimmune inhabitants, the disease may break out with epidemic violence. Such a possibility has already been appreciated, and appropriate legislation has been enforced by the Government of India to deal with such an eventuality In a publication dealing with this subject, Chowdhury and Ganguli (1937) have discussed the problems involved in the control of *Aedes aegypti* in Calcutta, with reference to dengue fever and the possible importation of yellow fever into India by air, and give particulars of the notification of the Government of India regarding yellow fever, which has been framed in the following terms:

"In exercise of the powers conferred by section 2 of the Epidemic Diseases Act 1897 (III of 1897), the Governor-General-in-Council, being satisfied that India is being threatened with an outbreak of Yellow Fever, is pleased to direct (1) that no person shall arrive in India by an aircraft within nine days of his being in an area in which Yellow Fever exists, or in which though the disease has not been clinically demonstrated there is presumptive evidence, as a result of mouse-protection tests, that the disease has occurred in that area, unless he has been protected by satisfactory inoculation, or previous attack of the disease, and (2) that no aircraft which started from or alighted in any such area shall enter India."

LEGISLATION FOR PREVENTION OF SPREAD OF YELLOW FEVER

Aircraft

Official regulations designed to prohibit the spread of infection are to be found in the articles of the International Sanitary Convention for Aerial Navigation, 1933, amended, 1944 These are so extensively circularized by the Epidemiological Information Bulletin of United Nations Relief and Rehabilitation Administration (UNRRA) that it is only necessary to quote the general provisions of regulations applicable to man in Article 36.

"(1) That persons suffering, or suspected to be suffering, from yellow fever shall not be allowed to embark on aircraft on international flight. (2) That they will take all possible measures to establish the existence or nonexistence of yellow fever within their territories For this purpose, in territories where endemicity of yellow fever is suspected, in cases where the person dies within 10 days from the onset of any undiagnosed febrile illness, it is important that a specimen of liver tissue be taken, if necessary by viscerotome, for histopathological examination In endemic areas a sample of blood for a yellow fever immunity test should, in addition, wherever possible, be taken from all persons suffering from an undiagnosed fever, and if the cause of the fever remains doubtful and the patient recovers a second sample should be collected at the end of the third week from the onset of illness (3) For the purpose of quarantine control, UNRRA in consultation with the governments concerned and, as regards the Western Hemisphere, with the Pan-American Sanitary Bureau, shall define the boundaries of endemic yellow fever areas (4) That they shall use their best endeavors to secure that all persons who are likely to land in an endemic yellow fever area shall be inoculated against yellow fever 10 days before arrival in the area and that, so long as such persons remain in the area, they shall be reinoculated every 4 years (5) (*a*) That inoculation against yellow fever shall be required for all regular staff employees and crews using authorized aerodromes situated in endemic yellow fever areas (*b*) That in areas in which yellow fever does not exist, but in which there may be conditions

CHAPTER XXXIX

CLINICAL MANIFESTATIONS OF YELLOW FEVER

CLINICALLY, yellow fever manifests itself as a single entity. For epidemiological purposes, outbreaks have been classified into different varieties according to the geographical surroundings in which the disease has been acquired. Hence the term "epidemic yellow fever" has been used to describe large outbreaks, affecting communities, caused by the insect vector *Aedes aegypti* (*Stegomyia fasciata*). The terms "urban" and "rural" have been applied to cases contracted in town and country respectively, whereas in the past the name "maritime yellow fever" has been reserved for outbreaks associated with ships and seaport areas Within comparatively recent times 3 new epidemiological descriptive terms have been added to the literature, namely the so-called "endemic," "sylvatic" and "jungle yellow fever." The former term has been designated for those cases occurring in the interior of South America, which once was thought to be free from the disease but is now known to be infected.

GENERAL CHARACTERISTICS

In tropical climates, cases are liable to occur throughout the year but in subtropical zones they are limited to the summer months Individuals visiting the forests and nonimmune new arrivals in endemic zones are vulnerable to attack.

Age and Sex Incidence

During the 1921 epidemic in Peru, Hanson (1929)[1] reported that the highest death rate occurred among young children from 1 to 3 years of age, and the mortality among this group was used to determine the endemicity of the disease at various centers. The death rate was lowest in those aged 5 to 15 years, and males appeared to be slightly more affected than females. In individuals over 50 years of age the prognosis was grave, and death usually occurred about the 6th day after the onset of symptoms.

Clinical Signs and Symptoms

The onset may be either sudden or insidious, being ushered in with a rigor in an individual who has previously been in good health, or else it may commence with an initial period of malaise. The subsequent course of the disease is usually divided into 3 clinical stages that exhibit different manifestations. These are (1) the initial fever, (2) the period of calm, and (3) the stage of reaction, if the attack is a severe one.

present The disease is highly infective in its early stages

Stage 2 is marked by the commencement of jaundice, it lasts from 1 to 3 days, the pulse and temperature may return to normal and complete recovery may result. In unfavorable cases vomiting of black colored blood and suppression of urine may supervene Such cases pass into stage 3, namely that of reaction. This may last about 7 days and the patient is usually critically ill. The temperature may rise

[1] References are appended at the conclusion of Ch. XLIII

"Article 36. Ships *infected* with yellow fever shall undergo the following measures: (1) Medical inspection. (2) The patients shall be landed, and those of them who are in the first five days of the illness shall be isolated so as to prevent infection of mosquitoes. (3) The other persons who land shall be subjected to observation or surveillance not exceeding six days reckoned from the time of landing (4) The ship will be moored at least 400 meters from the inhabited land and at such a distance from the pontoons as will render the access of *Stegomyia* improbable. (5) Mosquitoes at all stages of evolution shall be destroyed on board as far as possible before discharge of cargo. If unloading takes place before the destruction of mosquitoes, the personnel in charge of that work will be subjected to observation or to surveillance for not more than six days from the time when they ceased unloading"

CLINICAL PATHOLOGY

Albuminuria occurs early in the course of the disease and, when present, is of diagnostic value in doubtful cases, later on, the urine becomes reduced in quantity and may contain up to 2 gm of albumin per liter Additional data concerning the abnormal constituents of the urine in yellow fever are to be found in the work of Pichat (1929). Blood is present in the characteristic black vomit, as well as in the stools. A polymorphonuclear leukocytosis occurs in the initial stages of the illness and is later followed by leukopenia. Granular casts were present in the urine

Blood The percentage of polymorph leukocytes varied considerably, though in many cases their numbers were reduced. Lymphocytes were relatively increased. Hypoglycemia is often present and a rise in *blood guanidine* has been reported by Soper (1943)

DIFFERENTIAL DIAGNOSIS

In acute cases, the diagnosis is easy, and must be differentiated from other tropical diseases such as smallpox, measles (often fatal in colored races), influenza, dysentery, plague, pneumonia, Weil's disease, relapsing fever, typhus, scurvy and blackwater fever. In mild cases of yellow fever the disease is sometimes hard to identify, and the differential diagnosis from dengue fever has to rest on the results of leukocyte counts. Infective hepatitis can usually be excluded by the absence of marked constitutional signs and symptoms Carbon tetrachloride poisoning following antihelminthic treatment must be eliminated

MORBID ANATOMY OF YELLOW FEVER

The principal changes found at postmortem in a fatal case occurring in a nonimmune European (or other) subject are as follows

Icterus, hemorrhages into various organs, hemorrhages into the mucous membrane of the stomach; necrosis of the liver, degeneration of kidney tissue and discoloration of the urine Hindle (1930 *a*) states that the jaundice found at autopsy is lemon yellow in color, is conspicuous on the skin, conjunctivae, cartilages, the region of the larynx, over the great vessels of the heart, and, moreover, that the fat and loose tissues of the body are likewise discolored

[illegible]

necrosis The kidney [illegible]
albumin, bile, hyaline [illegible]
malpighian bodies are [illegible]
ent hemorrhages.

MORBID HISTOLOGY

Liver lesions are characteristic and diagnostic of the disease The changes have been described by Rocha Lima (1912), Hudson (1928), Torres (1928), Klotz and Belt (1930), and Hoffmann (1928, 1937) According to Bablet and Bloch (1937), tissues should be placed in Duboscq–Brasil's liquid for 24 hours, then embedded in paraffin, sectioned 5 μ thick, and stained by the following method. Mayer's hemalum 10 minutes, wash in water, differentiate in 90 per cent. alcohol containing 5 drops of HCl per 100 c c for a few seconds, wash in tap water for 5 minutes, stain in 1 per cent bluish eosin for 3 minutes, wash repeatedly in tap water. Stain and differentiate in alcoholic solution of safranine for 3 minutes, dehydrate in absolute alcohol rapidly, thereby removing the excess of safranine, treat with toluol, and mount in neutral Canada balsam

again, the pulse rate fall, and black vomiting develop. Prostration, anuria, melena, jaundice, and epigastric pains increase in severity, and death may end the scene Sometimes, before the end, indications of cerebral involvement such as delirium, convulsive spasms, and coma may become evident.

In cases which recover, the individual usually commences to improve about the 8th day after the beginning of illness, and thereafter convalescence may proceed in an uninterrupted fashion Relapses are frequent and dangerous when they occur Recovery from one attack confers lasting immunity against reinfection

There is no specific treatment for yellow fever.

YELLOW FEVER IN THE WEST AFRICAN NATIVE

The disease probably assumes a milder form in the African Negro Beeuwkes (1937) gives a good account of the clinical manifestations of the disease as he studied it during the course of 4 extensive epidemics affecting the Gold Coast and Nigeria Beeuwkes points out that in the past, the description of the disease was almost exclusively confined to its occurrence among Europeans, as cases among Africans were rarely observed except when an epidemic took place among the whites The number of cases reported among the black population has been relatively small, and the symptoms of the disease are often of so mild a character that extensive epidemics affecting the native population have frequently escaped recognition.

Clinical Findings

Males appeared to be more commonly attacked than females, and the death rate varied from 10 to 32 per cent. among individuals between 30 and 51 years of age

The duration of illness was usually from 8 to 9 days, and in fatal cases death occurred on the 7th day, being later in comparison with the time of death in the European subject.

Temperature lasted about 3½ days, it tended to be high at the commencement of the illness and thereafter gradually declined In mild cases the temperature reached about 104° F with a pulse of 120 per min In such cases Faget's pulse was absent, but a relatively slow pulse was observed in about 40 per cent. of instances

According to Maegraith (1946), Faget's description mentions 2 signs (1) an initial diagnostic sign, slowing pulse rate with rising temperature, and (2) a final evil prognostic sign, quickening pulse rate with fall in temperature

Headache and bodily pains were invariably present *Anorexia* was a prominent symptom *Vomiting* was marked only in the severe cases, but was of a transient character in the milder infections *Epistaxis* was rarely seen, and bleeding gums were less common than in the European *The degree of prostration* evident in different cases varied considerably

Congested eyes were generally observed at the onset of the illness and persisted for 4 to 5 days

Icterus manifested itself by the presence of a slight golden tinting of the sclerae, and, when pronounced, it extended to the mucous membranes of the conjunctivae, mouth, and lighter cutaneous areas

Liver Tenderness was present, but the extent of enlargement of the organ could not be accurately elicited

The spleen was observed to be hard and enlarged, but whether or not this was due to the effects of malaria could not be determined

Tongue Beeuwkes stated that a tongue typical of yellow fever is "small, more or less pointed, with a white or brown coat over the division and definite red edges and tip . . ."

Albuminuria was present in every case and varied greatly in intensity.

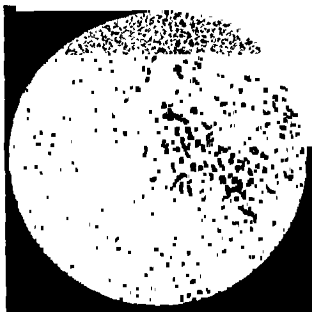

Fig 32 Photomicrograph of an histological section prepared from liver tissue removed from a fatal case of yellow fever. Note the extensive fatty degenerative change and the few recognizable liver cells Stained hematoxylin and eosin X90

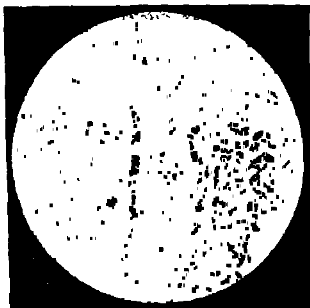

Fig 33 Histological section of kidney from a fatal case of yellow fever Note the lime cast in the center of the field Stained hematoxylin and eosin X90

An affected tissue section shows extensive coagulation necrosis, with fatty degenerative changes commencing in the mid-zonal area and extending to the portal and central veins (Rocha Lima, 1912). Often there are left intact a few layers of parenchymatous cells around the central vein in the peripheral parts of the lobule. The liver cells are extensively vacuolated, separated by spaces, and are markedly acidophilic in staining affinity. Here and there in the affected cells there appear large, rounded, granular, necrotic masses which have been named Councilman lesions, and a description of these is to be found in the work of Babler (1936, 1937) The nuclei of individual liver cells are damaged, being either disintegrated or showing such injury as loss of staining property margination of the chromatin, or the presence of acidophilic-staining material at their center. The latter have been called *the intranuclear inclusion bodies of Torres* (1928), and are most conspicuous in the early stages of yellow fever prior to the onset of advanced liver changes (see Cowdry and Kitchen, 1930).

Nicolau, Kopciowska, and Mathis (1934 *a*) studied the morphology of these inclusions, and found that they were oxyphilic bodies that lacked any internal structure and were sometimes surrounded by a halo in the karyoplasm In size, they varied from 1 to 4 μ in diameter, and several of them often appeared in a single cell These workers believed that the inclusion body represents the reaction of the nucleus against the virus which has entered the cell.

In addition to the above findings, minute hemorrhages are distributed throughout the liver parenchyma, the sinuses contain disintegrated leukocytes, and Kupffer cells may be seen lining their boundaries. The damage done to the Kupffer cells in yellow fever has been studied by Klotz and Simpson (1927), who reported that hyperplasia of these stellate cells was to be found in the late stages of the less severe cases, and their presence appeared to be associated with the existence of clinical jaundice. These cells also revealed other changes such as granular degeneration, pyknotic nuclei, and the presence of bile or iron pigment within their cytoplasm. In a later publication Klotz and Belt (1930) examined histological sections of liver derived from 93 fatal cases of human yellow fever, and declared that the vascular system, biliary channels, and stroma were unaffected in the disease.

In general it may be stated that the liver changes in yellow fever closely resemble those of acute yellow atrophy, and considerable experience is required on the part of the pathologist to arrive at a diagnosis of yellow fever from the results of microscopical examination alone (see Fig. 32)

The kidney Acidophilic necrosis of the tubular epithelium with fatty degeneration is present The glomeruli are congested and the renal tubules may contain hyaline, granular, or calcareous casts. Hoffmann (1937 *a*) attaches special significance to the existence of renal lime casts in yellow fever as a point of diagnostic value in suspected cases of the disease (see Fig 33). The general appearance presented by the organ as a whole is that of an acute toxemic reaction.

The regeneration of liver and kidney tissue following an attack of yellow fever has been studied in rhesus monkeys and is referred to in the appropriate section on p 499, describing the lesions produced in these animals

The brain Nicolau, Mathis, and Baffet (1937) examined histological sections of brain, prepared from a fatal case of yellow fever, which were stained by Mann's method, and recorded the following findings The meninges were normal, but there was proliferation of glial cells in both gray and white matter around the blood vessels Perivascular mononuclear infiltration was present around blood vessels and sometimes also surrounded isolated nerve cells Both the nerve cells and glial cells of the cerebral cortex contained eosinophil intranuclear inclusion bodies, and some of the latter were surrounded by a halo of nonstaining material. Lesions similar to these were also detected in the brains of monkeys, guinea-pigs, and mice after experimental infection with yellow fever virus (Nicolau, Mathis, and Baffet, 1936). The histopathology of the brain and spinal cord of 14 fatal cases was con-

reactions and serum protection tests have also proved that no antigenic differences exist between the yellow fever virus of the western hemisphere and that of Africa (Theiler and Sellards, 1928, Hudson, Philip, and Davis, 1929; and Hudson, Bauer, and Philip, 1929).

The Value of Routine Liver Examination and Use of the Viscerotome

The *viscerotome is a metal instrument (see Fig 34) resembling a trocar, about* 1 cm. square, possessing a sharp, hollow, pointed extremity fitted with a mechanically operated guillotine blade. Thus, by plunging the sharp end into the right epigastric region of a cadaver it is possible to extract a piece of liver tissue without the *inconvenience of having to perform* a postmortem examination. Specially constructed viscerotomes are also available for obtaining blocks of kidney tissue or other organs Recently, in South America, a regular viscerotomy service has been inaugurated, and legislation has been introduced whereby officials of the yellow fever service have been authorized to remove specimens of liver from all persons dying after any illness of less than 10 days' duration (see Soper, Rickard, and Crawford, 1934).

Soper states that up to 1936 more than 65,000 viscerotomies have been per-

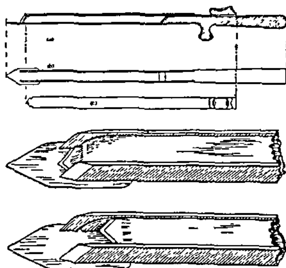

FIG. 34 Diagram illustrating the construction of the viscerotome

(Reproduced from Soper, Rickard, and Crawford, 1934, Amer J Hyg, 19, 549)

formed in about 1,500 places in Brazil, Bolivia, Paraguay, Ecuador, and Colombia.

The *outcome of the routine* examination of liver tissue from all fatal pyrexias information, thus justify- the existence of yellow uzed, and cases are discovered among natives, foreigners, adults, and in children resident in urban and jungle areas, situated both within and without known endemic localities (see Rickard, 1937).

ducted by Stevenson (1939). The principal lesions were perivascular hemorrhage affecting the subthalamic and periventricular region at the level of the mamillary bodies The temporal pole and cerebellum were involved to a lesser extent and similar changes were seen in the hippocampus and lumbar region of the spinal cord. Perivascular edema and sclerosis of ganglion cells of the superior frontal gyrus also occurred.

The pituitary body is engorged with blood, the tissue is markedly degenerate, and petechial hemorrhages are scattered throughout the white substance (Marchoux and Simond, 1906 *b*).

Heart. This organ was examined in 29 fatal cases of yellow fever occurring in West Africa by Cannell (1928), and cloudy swelling and fatty degeneration were the most constantly found features The distribution of the latter was patchy in character and most marked in the neighborhood of nuclei of the fibers Primary inflammatory changes were usually absent in yellow fever, but secondary response of white cells to intense degenerative changes was observed in 2 human cases The lesions occurring in the heart, when considered as a whole, are not sufficient to warrant a diagnosis of yellow fever being made on their presence alone From the results of his investigations into the state of the heart in yellow fever, Cannell is unable to find any reason to account for the existence of a slow pulse rate which is sometimes manifest in this disease. He believes that bradycardia is not due to concurrent jaundice and that examination of the bundle of His may conceivably shed some light on the problem (see also Marchoux and Simond, 1906 *c*)

Spleen Klotz and Belt (1930 *a*) noted the absence of hyperplasia in the fixed tissues of the pulp and observed the presence of certain changes in the malpighian corpuscles of the organ. In the latter, there were present mononuclear cells accompanied by reduction in the number of lymphocytes of the spleen, hyperplasia of the fixed tissues of the follicle, and waxy degeneration of the organ. A moderate degree of eosinophilia was detected in cases where the pathological lesions were advanced.

The pancreas, body *of the testicle, spermatic cord,* and *suprarenal glands* show
[illegible] *lacrimal, salivary,* and *thyroid glands* re-
[illegible] are less likely to occur in these organs
[illegible]

LABORATORY DIAGNOSIS

Sterile blood should be obtained within the first 3 days of fever, packed in ice, transmitted to the laboratory and inoculated subcutaneously or intraperitoneally in rhesus monkeys. In positive cases the latter develop fever after 3 days and may die thereafter exhibiting typical liver lesions On the first day of the patient's illness sterile serum should also be removed, the mouse protection test performed and the operation repeated 5 days later to ascertain if rise in antibody titer has occurred

The liver lesions found in a fatal case of yellow fever are diagnostic of the condition.

Tissue should be removed at autopsy, placed in 10 per cent formalin in physiological saline, embedded in paraffin, sectioned and stained by the methods described. The existence of the microscopic lesions mentioned previously is conclusive evidence of infection According to Bablet and Bloch (1937), the most diagnostic features are the presence of Councilman lesions, hyaline necrosis of liver cells, and total disappearance of nuclear chromatin. The finding of intranuclear inclusion bodies clinches the diagnosis of yellow fever, but it is not always possible to demonstrate these structures

The identity of American and African yellow fever The pathological lesions caused by the virus isolated in either country are similar in their general characteristics, but Klotz and Belt (1930 *b*) have pointed out that individual strains are sometimes liable to vary For convenience, it may here be noted that cross immunological

CHAPTER XL

YELLOW FEVER IN SOUTH AMERICA

Previous Epidemics[1]

BELOW is a record of outbreaks during the twentieth century in Central and South America, with dates of introduction of antimosquito legislation in different areas, and approximate numbers of cases of yellow fever prevalent at that time.

1893–1900 Havana, Vera Cruz, Isthmus of Panama, Rio de Janeiro
1900 Antimosquito measures were inaugurated at Havana (310 cases, population 300,000)
1902–3 Vera Cruz, Isthmus of Panama, Rio de Janeiro, Guayaquil
1904 Antimosquito measures were inaugurated at Vera Cruz (375 cases; population, 45,000)
1904–8 Havana, Vera Cruz, Isthmus of Panama, Rio de Janeiro, Para, Manaos, Guayaquil
1905 Antimosquito measures were inaugurated at Isthmus of Panama and at Rio de Janeiro (289 cases, population 1,000,000)
1907–9 Martinique
1908–13 Para, Manaos, Guayaquil
1910 Antimosquito measures were inaugurated at Para (358 cases, population 200,000)
1913 Antimosquito measures were inaugurated at Manaos (96 cases, population 60,000)
1913–17 Guayaquil (over 505 cases, population 54,000)
1915–16 Merida (Yucatan) Mexico, a few cases
1917 Merida and Peto (Yucatan) Mexico, a few cases only
1918 Antimosquito measures inaugurated at Guayaquil
1920–4 Mexico, Central America, Colombia, Peru, Brazil
1925–7 Brazil
1928 Rio de Janeiro, North Brazil
1929 South Brazil, São Paulo, South Para, at the mouth of the Amazon in the north The disease extended for over an area of 1,000 miles from Buenos Aires to Manaos. (A good example of so-called "maritime" yellow fever)
1929 Yellow fever reappeared in the interior of Colombia and Venezuela after an absence of 6 years
1929–30 Cases were recognized at only one point well away from the coast of Brazil in a well-isolated area
1930 The year marked the introduction of viscerotomy (Soper, Rickard, and Crawford, 1934), and the development of the mouse protection test (Sawyer and Lloyd, 1931)
1933 There were 3 confirmations of the possibility of yellow fever without *Aedes aegypti*, from widely separated areas at San Ramon (Bolivia), Lavro Sadre in Brazil, and at Caparrapi in the Magdalena Valley of Colombia.
1934 Yellow fever transmitted by *A aegypti* was relatively unimportant. Jungle yellow fever, on the other hand, was reported in Magdalena and Orinoco river valleys in Colombia (Soper, 1936), and at 3 points in Brazil at Para, Bahia, and Matto Grosso (Soper, 1936)
1935 Yellow fever transmitted by *A aegypti* was only proved to exist at one point in South America (in Minas Geraes, Brazil) (Soper, 1936)

[1] References are appended at the conclusion of Ch XLIII, p 511 et seq

Positive results indicate the exact spot at which infection exists, and so provide a starting point for the inquiries of the health authorities. Negative reports, on the other hand, are equally informative, as a long succession of negative reports from any one area indicates the absence of the disease. The value of viscerotomy in the diagnosis of other pathological conditions has been reported by Gast-Galvis (1945)

decline, Soper suggested that this was probably attributable to inefficiency of the insect vector rather than to a failure of human hosts. Subsequently Soper (1936) and others actively investigated the subject, and defined the jungle disease as "yel-

FIG 35 South American yellow fever area, delineated by Expert Commission on Quarantine. Since the publication of this map, minor changes have been made, particularly as regards the areas delineated in Brazil (*Epidem Inform Bull*, 1946, *2*, 580, 689, 772).

(Reproduced from *Epidem Inform Bull*, 1945, *1*, 687, by permission of the Executive Secretary, Interim Commission, World Health Organization.)

low fever occurring in rural jungle or fluvial zones in the absence of *Aedes aegypti*."

There are many points of distinction between epidemic or rural yellow fever and jungle yellow fever apart from the fact that the former is transmitted by *Aedes*, whereas the latter is not. Thus, yellow fever transmitted by *Aedes* is usually

1936 In this year James (1936) reported the occurrence of 16 cases in Bolivia, and 179 in Brazil

1944 Jungle yellow fever occurred in the state of Barinas Bolivar and Tachira, Western Venezuela (Diaz, 1945). So successful have been the anti-mosquito measures that in recent decades the boundaries of yellow fever have considerably regressed and in the year 1934 urban *Aedes aegypti* transmitted yellow fever was only present at a single center in Brazil Thus, the urban *Aedes* transmitted disease, one trusts, will not recur, and the problem of jungle yellow fever next awaits conquest.

GEOGRAPHICAL DISTRIBUTION

The potential distribution of yellow fever liable to arise from jungle sources based on clinical, pathological, and serological information is shown in Fig 35. (See de Paula Souza, 1945.)

"For the purpose of quarantine control, the areas in the South American continent, which for the time being should be considered as endemic yellow fever areas, are bounded by a line beginning on the Pacific coast of Colombia at the 5° N. parallel of latitude and extending east along that parallel of latitude to the eastern slopes of the Central Cordillera to an elevation of 2000 meters, thence southward along the eastern slopes of the Central Cordillera and the Andes Mountains, at the same elevation to the boundaries of Argentina and Bolivia, thence eastward along the southern boundary of Bolivia with Argentina and Paraguay to the 20° S parallel of latitude, thence east along that parallel in Brazil to the eastern border of the State of Mato Grosso, thence southward along the eastern boundary of the State of Mato Grosso to the 21° S parallel of latitude, thence east along that parallel to the 45° meridian of longitude, thence north along that meridian to the 15° S parallel of latitude, thence west along that parallel to the western boundary of the State of Goiaz, thence northward along that boundary of the State of Maranhao to the Atlantic coast, thence along the Atlantic and Caribbean coasts of South America to the eastern boundary of the Canal Zone, thence southward across the Isthmus of Panama and along the Pacific coast of Panama and Colombia to the 5° N parallel of latitude, excluding, however, the ports of Belem in Brazil, Cayenne in French Guiana, Paramaribo in Surinam, Georgetown in British Guiana, and the Caribbean ports of Colombia and Venezuela, and the cities of Caracas in Venezuela, Bogota in Colombia, and Corumba in Brazil

"In addition, the Ilheos and Itabuna Districts in the State of Bahia in Brazil bounded on the north by the River Contas, on the west by the 40° meridian of longitude, on the south by the River Pardo and on the east by the Atlantic Ocean, are for the time being, regarded as endemic yellow fever areas" (de Paula Souza, 1945)

ETIOLOGY OF JUNGLE YELLOW FEVER

During the year 1933 the results of an important discovery made during the course of their researches in Brazil were announced by Soper, Penna, Cardoso Serafim, Frobisher, and Pinheiro (1933) These workers for the first time drew the attention of the scientific world to a rural outbreak of yellow fever occurring in Valle do Chanaan, Espirito Santo, Brazil, during which *Aedes aegypti* could be eliminated as the insect vector Certain other mosquitoes were, however, found to be present in the locality, but the only 2 species to be viewed with suspicion were *A* (*Ochlerotatus*) *scapularis* (Rondani) and *A*. (*Taeniorhynchus*) *fluviatilis* (Lutz), of which Soper and his colleagues believed the first to be more dangerous than the second Both have been confirmed as efficient vectors of yellow fever by Whitman and Antunes (1937 a)

The results of mouse protection tests performed on the sera of several hundreds of residents in Valle do Chanaan also yielded interesting results, for, although previous epidemics had invaded that locality, the percentage of positive sera was surprisingly low. The disappearance of the disease from the district was as mysterious as the circumstances surrounding its arrival, and in explanation of its spontaneous

sued. Monkeys and mosquitoes are responsible for jungle yellow fever. Special attention has been paid to the occurrence of natural epidemics of yellow fever with high mortality affecting the Howler species of monkey which is present throughout the entire tropical region of South America Bauer (1939) has described how wild monkeys were trapped, bled for protection tests, tattooed on the ear, liberated, subsequently recaptured (some as many as 6 times) and reexamined for possible changes in antibody content. Certain species could be infected experimentally and a high enough concentration of virus appeared in the blood to infect mosquitoes, but as a group, the density of the entire monkey population in any one region seemed inadequate to sustain infection for any considerable length of time Again, at Maracaju in southern Matto Grosso, the narrow strip of forest along the streams supported such little wild life as to render animal reservoirs of infection improbable. Soper (1943) has expressed a different point of view and believes that the Howler monkey which succumbs to infection is less likely to spread infection than, for example, the Cebus monkey which circulates virus in its blood stream and so acts as a source for dissemination of virus.

At Para Brazil, in an area of jungle yellow fever, 10,121 adult mosquitoes and 1,260 larvae, representing 80 different species, were collected by Kumm and Novis (1938). No *Aedes aegypti* were found and the most common species observed to bite man by day were *Aedes nubilis*, *Psorophora ferox*, and *Haemagogus janthinomys*

Subsequent investigations on jungle yellow fever near the towns of Villavicencio and Acacias in Eastern Colombia by Bugher *et al.* (1944) have confirmed and amplified earlier etiological and epidemiological studies. No *Aedes aegypti* were found, but *Haemagogus capricornii* was found to be carrying virus on 13 occasions and *Aedes leucocelaenus* once No virus was found in any other arthropod form. Immunity tests on the sera of monkeys and the marsupial *Didelphis marsupialis* revealed that they had suffered from a recent outbreak of infection So it was concluded that jungle yellow fever can be sustained among monkeys, marsupials, or both of them, but no proof was found to indicate that these creatures constituted a reservoir of infection There was more evidence to suggest that virus survived during the dry months in *H capricornii* in which it persisted from one rainy season to another (Gast and Bates, 1945) In contrast, the behavior of yellow fever virus in *Aedes aegypti* has been found to be very different, since Davis and Shannon (1931) observed that virus was unable to survive in a fixed colony of *A. aegypti* They concluded that it seems practically certain that in nature yellow fever is not self-propagated among *Stegomyia* mosquitoes and that these insects could not maintain quantities of yellow fever among themselves without the aid of intermediate hosts More recent studies by Laemmert, Ferreira, and Taylor (1946) in Brazil forests show that virus is maintained by the primate-mosquito (*Haemagogus*) cycle Thus, the present problem is that of jungle yellow fever and the periodic introduction of infection into cities and towns by country laborers, where, should *Aedes aegypti* be present, household epidemics may ensue.

The taxonomy of the *Haemagogus* group of mosquitoes is at present being investigated In Argentina, researches showed that *Haemagogus janthinomys* (Dyar 1921) should be considered a synonym of *H. spegazzinii* (Brèthes 1912) and not a synonym of *H. spegazzinii* (Lutz) as previously suggested (Cerqueria and Boshell-Manrique, 1946) In Brazil, the geographical distribution of *H spegazzinii* and *H. uriartei* (Shannon and del Ponte) and *H capricornii* are more restricted. The Villavicencio population of mosquitoes referred to by Bates and Roca Garcia (1946 *a*) as *Haemagogus capricornii* has been identified as *Haemagogus spegazzinii* by Kumm, Osorno-Mesa and Boshell-Manrique (1946). The latter add that no less than 8 species of *Haemagogus* were found in Colombia, the commonest and most widely distributed of which was *H spegazzinii falco*

a "house disease," being contracted by individuals who visit patients in infected houses in towns or cities, and direct evidence to this effect has been furnished by Beeuwkes and Hayne (1931), who proved the presence of yellow fever virus in mosquitoes captured in African towns. Jungle yellow fever, on the other hand, is invariably contracted by persons dwelling in close proximity to forests or jungle clearings. The circumstances in which persons living amid such surroundings acquire infection enable an epidemiological distinction to be drawn between jungle yellow fever and that transmitted by *A. aegypti*. The evidence has shown that in people dwelling on the outskirts of a forest who develop the disease, infection can often be traced back to the date on which the individual entered a particular plot of jungle land. The natives of South America have themselves observed the risk of infection accompanying visits to certain fields and clearings, and Soper (1936) quotes 2 instances in which the inhabitants of a district abandoned harvesting the crop of a particular field because they knew it was dangerous to work there.

The comparative age distribution of the 2 diseases is also significant and again points to infection being acquired away from houses. *Aedes*-transmitted yellow fever tends to attack both young and old indiscriminately, but with jungle yellow fever its incidence is low among children from 1 to 4 years of age, and cases are limited to those youngsters who are sent out of doors bearing messages or food to their parents working in the forests. The highest incidence of the disease was recorded among able-bodied agricultural workers between the 2nd and 4th decades of life, also in girls of 15 to 19 years of age, just at the time when they had begun to assist their menfolk in the fields. In the case of smaller communities living in the midst of large jungles, the peculiar age distribution is absent, and here the disease appears to be endemic throughout the whole population.

Unmarried men in Colombia who are employed as itinerant woodcutters and laborers constructing roads through the forest are so frequently attacked that the illness is popularly referred to by them as "bachelor's disease." Other points of interest are that the insect vector does not enter houses built as close as 300 feet to the forests, and, furthermore, secondary cases do not develop in the homes of victims (Bauer, 1939). The next advance was made in 1938 by Shannon, Whitman, and Franca, who captured 3 species of mosquitoes at the site of an outbreak of jungle yellow fever near Rio de Janeiro and demonstrated the presence of yellow fever virus in *Aedes leucocelaenus*, *Haemagogus capricornii*, and an unidentified species of *Sabethine* mosquito. These insects breed in the holes of trees, the bromeliad and other parasitic flora of tropical forests. The distribution of *Haemagogus capricornii*, believed to be the principal diurnal vector of jungle yellow fever in Eastern Colombia, has been investigated by Bates (1944a), and found to exhibit maximum activity at midday and be relatively more numerous in the forest canopy than at ground level. *Psorophora ferox*, on the other hand, showed morning and afternoon activity. *Aedes scapularis* which breeds in grassy pools and readily transmits yellow fever under laboratory conditions, is thought to be responsible for man to man infection in rural areas and even for jungle yellow fever in flat forest zones, according to Soper (1943). At Villavicencio in Eastern Columbia, Gast and Bates (1945) correlated the incidence of human cases with seasonal fluctuation of the mosquito population, the rainy season, and the occupation of woodcutting. Thus the peak of human cases occurred in November and December, and reached their lowest ebb at the end of the dry season in March when *Haemagogus* mosquitoes were relatively scarce. Bauer (1939) mentions that the disease may be prevalent either in the tropical rain forest type of vegetation of Colombia and the Amazon or amid the shrubby grasslands and streams of southern Matto Grosso and Minas Geraes in Brazil.

The search for animal reservoirs of infection (Gilmore, 1943) among all species of wild animals inhabiting the forests of South America has been intensively pur-

fected Cebus monkeys (*Cebus versutus*), (3) by use of *Haemagogus equinus* and *H. spegazzinii* fed on marmosets. The latter insects would not breed in the laboratory. The susceptibility of primate *Leontocebus chrysomelas* in Brazil to infection was shown by Waddell and Taylor (1946) who also demonstrated presence of virus in captured C. *penicillata* on 4 separate occasions. A strain of jungle yellow fever virus was propagated for 7 cycles in *H. equinus* mosquitoes with C. *aurita* and C. *penicillata* marmosets. Under laboratory conditions *A aegypti* appeared to transmit infection more readily (by biting) than *H. equinus* (Waddell and Taylor 1947). See also Laemmert and Ferreira (1945).

Haemagogus splendens, found in Colombia, was able to transmit yellow fever under laboratory conditions to saimiri and douroucouli monkeys captured in Villavicencio. To infect mosquitoes peripheral blood of the monkey should attain a minimum concentration of 10^{-4} dilution of virus pathogenic to mice (Anderson and Osorno-Mesa, 1946).

FACTORS AFFECTING CONTROL OF YELLOW FEVER

The present situation concerning yellow fever in South America has been epitomized by Soper (1943) and Sawyer (1940) as follows·

(*a*) Absence of *Aedes aegypti* transmitted infection affecting cities, towns, villages and strictly rural areas.

(*b*) Yellow fever without *Aedes aegypti* occurring in individuals visiting the forests where the density and movement of population is so low that human cases can be incidental to an epizootic among jungle animals. Also the very rare rural type of disease suggesting a simple man-vector-man mechanism of transmission.

(*c*) Jungle transmitted yellow fever as endemic and migrating epidemic in wide areas in the interior of S. America.

(*d*) Effective methods for keeping cities free of infection by anti-*aegypti* measures.

(*e*) Active immunization of persons liable to convey infection from the forests into towns.

(*f*) Absence of recognized yellow fever of any transmission type outside S. America.

Soper (1943) states that "there is reason to believe that jungle yellow fever is the original epidemiological type and that the *aegypti*-transmitted variety is a recent and exotic development" Work in Brazil has demonstrated how *Aedes aegypti* eradication is feasible when the money, men, and authority are available for control measures. Indeed, so successful have these measures been that the *aegypti* transmitted disease, originating from previous *aegypti* transmitted yellow fever, has been absent from South America since 1934. But *aegypti* transmitted infection secondary to immediately preceding jungle yellow fever has been observed as recently as 1937 and constitutes the principle threat to control measures.

The South American continent contains vast areas of jungle yellow fever infection and the dream of yellow fever eradication from the Western Hemisphere, through anti-*aegypti* campaigns, has not been realized because jungle animals have maintained an uncontrollable reservoir of infection.

Jungle Vertebrates and Spread of Infection

Bugher, Boshell-Manrique, Roca-García, and Gilmore (1941) studied the susceptibility of certain vertebrates of the Villavicencio-Restrepo-Acacias region of Eastern Colombia to yellow fever virus. The following New World marsupials of the family Didelphidae (opossums) were shown susceptible to the virus of yellow fever and some developed antibodies after recovery, suggesting that they may be vital links in the complex epidemiological picture of jungle yellow fever in Colombia. Genus 1, *Didelphis* (Linnaeus), 1758 Large, common opossum, "chucha," "fara," "runcha" (Colombia). Species tested were *Didelphis marsupialis* and *Didelphis paraguayensis*. Genus 2, *Philander* (= *Metachirops* auct) Brisson, 1762. Gray masked opossum; "chucha real" (Colombia). According to Laemmert (1946) *Didelphis marsupialis*, *Didelphis paraguayensis*, and *Metachirops opossum* are relatively insusceptible to infection Genus 3, *Metachirus* (Burmeister, 1854). "Chucha real" (Colombia) closely resembling *Philander* save for longer tail and browner coloration *Metachirus nudicaudatus*. (Geoffroy, 1803), was examined. Laemmert (1946) also reported that *Metachirus nudicaudatus* and *Marmosa incana* could be readily infected. *Marmosa cinera* was partially susceptible. Genus 4, *Chironectes*, the water opossum, and Genus 5, *Lutreolina*, the weasel opossum, were not tested Genus 6 *Caluromys* (=*Philander* auct) Allen, 1900. Brown or woolly opossum *Caluromys* (*Mallodelphis*) *laniger*. Genus 7, *Marmosa* (Gray, 1821). Long, bare-tailed murine opossum. "Chucha raton" (eastern Colombia). Common to Central and South America

At Villavicencio, the *Saimiri sciureus caquetensis* monkey also referred to as the "squirrel" monkey in English, and "mico titi" in Colombia, was proved to be highly susceptible to yellow fever virus infection The maximum titer of virus in circulating blood was found to reach a dilution of 1 1,000,000 and about 33 per cent succumbed to infection (Bates, 1944 *b*). The brown masked opossum *Metachirus nudicaudatus* was found susceptible to intramuscular injection, and a Colombian strain of yellow fever virus was maintained for 10 consecutive passages in this animal. The serum of the latter was toxic to mice by intracerebral inoculation The gray masked opossum, *Metachirops opossum*, was resistant (Bates, 1944 *c*) Marmosets *Callithrix leucocephala* (E Geoff), *Callithrix jacchus* (L) and the lion marmoset *Leontocebus rosalia* have been shown to develop fatal infections (Laemmert, 1944) The cane rat, *Zygodontomys stella*, indigenous to Villavicencio, is also susceptible to intracerebral inoculation with yellow fever virus (Bates and Weir, 1944). See also Laemmert (1946) for susceptibility of marsupiala to different strains of yellow fever virus

Cyclical Transmission Experiments

Subsequent studies in Colombia by Bates and Roca-García (1946 *a*) on insects and mammals indigenous to those lands, have shown that the virus of sylvatic yellow fever could be maintained for one year of 14 cycles, by alternate passage through insects and mammals.

The infective cycle was readily demonstrated employing saimiri or douroucouli (*Aotus trivirgatus*) monkeys said to be the only species of monkey prevalent in Eastern Colombia where yellow fever is endemic (Bates and Roca-García, 1945). Also the marmoset *Oedipomidas oedipus* Virus circulates in the blood of monkeys for 7 to 8 days and in *Haemagogus capricornii* for the duration of its life The mosquito, therefore, appears to be a permanent reservoir of yellow fever virus In the Ilhéos region of Balna, Brazil, yellow fever virus has been isolated both from the wild marmoset (*Callithrix penicillata*) and the mosquito *Haemagogus spegazzinii* (Laemmert, Ferreira and Taylor, 1946) and cyclical transmission was also demonstrated in 3 other ways by Waddell and Taylor (1945) (1) by feeding *Aedes aegypti* on infected *Callithrix aurita*, (2) by feeding *Aedes aegypti* on in-

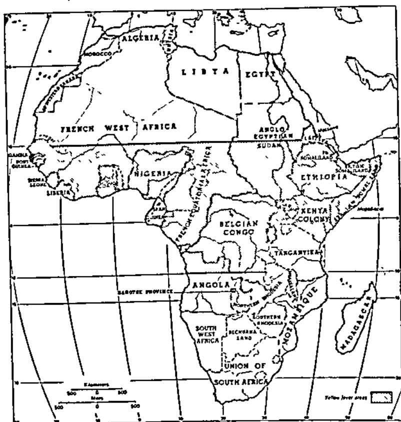

Fig. 36 African yellow fever area, delineated by Expert Commission on Quarantine Minor changes have since been made in Eritrea and N Rhodesia

(Reproduced from *Epidem Inform Bull*, 1945, *1*, 689)

no evidence of infection in Tanganyika and Zanzibar; Abyssinia is yet to be surveyed

After a lapse of 10 years, active work was renewed at the Yellow Fever Research Institute, Lagos, Nigeria (1945). Only one case was reported in 1942, but there was reason to suspect that the disease had been widespread among Africans throughout Nigeria south of latitude 10° N. Several thousands of cases are said to have occurred and the difficulty of recognizing infection in the African was stressed. Europeans appear to have escaped the disease, in all probability due to the efficacy of vaccination.

Does Jungle Yellow Fever Exist in Africa?

There is no absolute proof that the jungle variety of disease (analogous to that occurring in S America) exists in Africa. More than 150 years ago Lind (1792), a surgeon with the Royal Navy, reported that when the sloop *H.M.S Merlin* lay at anchor in the Gambia River in August, 1768, only those sailors who went into the forests to fell wood contracted yellow fever, whereas men remaining on board escaped.

Recent accounts suggest that hitherto unrecognized jungle yellow fever may be prevalent in Africa.

CHAPTER XLI

YELLOW FEVER IN AFRICA

From 1810 to 1878 Hirsch (1883)[1] reported successive epidemics of yellow fever in Senegambia, Sierra Leone, the Gold Coast, Teneriffe, Las Palmas, The Cape Verde and Ascension Islands (see also Boyce, 1910). In subsequent years the case incidence has declined, and in 1936 only 11 cases were reported from Dahomey, Guinea, Ivory Coast, Niger Territory, and Senegal, with 9 cases from the British Colonies including Sudan, the Gold Coast, and Nigeria. In 1940 an extensive epidemic of yellow fever occurred in Nuba Mountains region of Anglo-Egyptian Sudan (Kirk, 1941). In Western Uganda an important focus of disease was discovered in that part of the valley of the Semliki River to the west of the Ruwenzori Mountains which embraces the most easterly reaches of the Ituri forest of the Bwamba country, by Mahaffy, Smithburn, Jacobs, and Gillett (1942).

For official information of the endemic areas of yellow fever the reader should consult the periodical Epidemiological Information Bulletin published by the United Nations Relief and Rehabilitation Health Division. The last announcement delineated the African area of infection as follows

From the mouth of the River Senegal along that river eastward to the 15° N. parallel of latitude, thence eastward along that parallel to the eastern border of the Anglo-Egyptian Sudan, thence northward along the northwestern boundary of Eritrea to the Red Sea Coast, thence southward along the eastern coast of Africa to the southern boundary of the Protectorate of Kenya, thence westward along that boundary and the southern boundary of Kenya Colony to its junction with the southern border of the Uganda Protectorate, and thence along this and the eastern border of the Belgian Congo to the 10° S parallel of latitude, thence westward along that parallel to the west coast of Africa, thence northward along the west coast of Africa to the mouth of the River Senegal including the islands of the Gulf of Guinea The port of Massawa in Eritrea is excluded (de Paula Souza, 1945)

The African area can be divided into 2 parts. The western area extending from Nigeria to Angola where urban outbreaks are due to *A aegypti* (Beeuwkes *et al*, 1934) The eastern area lies between the latitudes of 3° and 8° N. extending from the eastern French Cameroons across French Equatorial Africa, overlapping northern Belgian Congo and into Anglo-Egyptian Sudan as far as Rumbeck. Within this area Sawyer and Whitman (1936) have reported high prevalence of immunity among children and adults North and south of the above territories there is a diminishing incidence of immunity Tests suggest the absence of immunity in southeastern Belgian Congo and Angola The Barotze Province of N. Rhodesia appears to be an island of infection surrounded by healthy country. De Paula Souza (1945) states that "the danger of the disease spreading eastward to seaports on the Indian Ocean demands much greater caution in determining the marginal areas of infection in Africa than doing so in S America." Thus it is safer to extend the area of quarantine to the Indian Ocean and Italian Somaliland The distribution of immunity to yellow fever in central and East Africa is described by Mahaffy, Smithburn, and Hughes (1946) They report that yellow fever has occurred recently in Belgian Congo, Anglo-Egyptian Sudan, Eritrea, Somalia, Kenya, and Northern Rhodesia Positive mouse protection tests were returned from as far east as Eritrea on the Red Sea, and to the south from Balawao in N Rhodesia. There has been

no evidence of infection in Tanganyika and Zanzibar, Abyssinia is yet to be surveyed.

After a lapse of 10 years, active work was renewed at the Yellow Fever Research Institute, Lagos, Nigeria (1945). Only one case was reported in 1942, but there was reason to suspect that the disease had been widespread among Africans throughout Nigeria south of latitude 10° N. Several thousands of cases are said to have occurred and the difficulty of recognizing infection in the African was stressed Europeans appear to have escaped the disease, in all probability due to the efficacy of vaccination

Does Jungle Yellow Fever Exist in Africa?

There is no absolute proof that the jungle variety of disease (analogous to that occurring in S America) exists in Africa More than 150 years ago Lind (1792), a surgeon with the Royal Navy, reported that when the sloop *H.M S Merlin* lay at anchor in the Gambia River in August, 1768, only those sailors who went into the forests to fell wood contracted yellow fever, whereas men remaining on board escaped

Recent accounts suggest that hitherto unrecognized jungle yellow fever may be prevalent in Africa.

Smithburn and Haddow (1946) isolated virus from *Aedes simpsoni* caught in 1942 in a forest plantation in western Uganda 11 months after mass immunization of the human population Virus was again isolated in 1944, from a lot of 80 *Aedes* mosquitoes including 12 different species, but not including *Aedes aegypti* or *A simpsoni*. The latter were collected in the uninhabited Semliki Forest, indicating an extrahuman cycle of virus activity, involving a forest vector. Sawyer (1940) holds that both S. America as well as Africa contain endemic regions from which yellow fever escapes from time to time to start urban *aegypti* transmitted epidemics and to spread through the paths of commerce.

Data suggested that human infection was associated with contact with the forest, and Mahaffy, Smithburn, Jacobs, and Gillett (1942) showed that in the Bwamba uninhabited forest region there were 4 species of mosquitoes known to be potential vectors of yellow fever, namely *Eretmopodites chrysogaster* (Graham), *Aedes (Stegomyia) simpsoni* (Theobald), *Taeniorhyncus (Mansonioides) africanus* (Theobald), *Aedes (Stegomyia) africanus* (Theobald). The last named species is by far the most prevalent, it breeds in plant axils and is found in bananas, pineapples, dracaena and colocasia, a widely cultivated food plant. It is not found inside houses but in their immediate vicinity. See also Haddow, Gillett, and Heighton (1947). The abundance, distribution, and feeding habits of some West African mosquitoes has been described by Kerr (1933).

Mahaffy *et al.* (1942) have summarized the position in Africa as follows "There are many gaps in our knowledge of the epidemiology of yellow fever in Africa and the whole problem requires further intensive study The possibility of the virus being able to maintain itself in sparsely populated or even uninhabited areas cannot be excluded. It may be that there are reservoirs of infection as yet unknown. The lore of yellow fever epidemiology associates forests and rainfall with outbreaks of the disease in a nonurban population. The experience in Africa strongly supports the importance of both these factors, but it has been found that some areas with forests and adequate rainfall manifest much less activity than others quite similar in these respects. The factors responsible for these variations in the virus in different areas in Africa are at present not known." According to Smithburn and Haddow (1946), in Bwamba the red tail monkey *Cercopithecus nictitans mpangae* Matschie, which frequently raids banana plantations may establish an extra human cycle of infection with *Aedes africanus* occurring in the forest canopy. At Gede, a settlement 65 miles north of Mambasa 3 miles from the sea, 3 species of acrodendrophilous mosquitoes, namely, *Aedes (Diceromyia) adersi*, *taylori*, and *furcifer*, have been suspected as jungle vectors of yellow fever (Bailey, 1947).

Some conception of the magnitude of the task confronting the investigator of jungle yellow fever in Africa is well illustrated in the complexity of the prevailing mosquito problem in Anglo-Egyptian Sudan Lewis (1947), has reported the occurrence of 140 known species, divisible into 3 categories (*a*) those which bite man readily (39 species), (*b*) those common to certain areas but which seldom or never attack man (18 species), and (*c*) a group comprising 9 species of which more information is sought

There exist 12 species capable of transmitting yellow fever by bite and these are *Taeniorhyncus africanus*, *Aedes aegypti*, *A aegypti* var *queenslandensis*, *A. simpsoni var lilii*, *A metallicus*; *A africanus*, *A leuteocephalus*; *A. vittatus*, *A stokesi*; *A taylori*; *Eretmopodites chrysogaster*, and *Culex fatigans* Equally important in the chain of possible jungle reservoirs of infection are 2 species *Taeniorhyncus uniformis* and *Aedes lineatopennis* which remain infective throughout life but are incapable of transmitting infection by biting as far as can be determined *Anopheles gambiae* and *Aedes apicoargenteus* only retain virus for a short time The African grivet monkey, *Cercopithecus aethiops centralis* Neuman, can, in a proportion of animals, be infected with yellow fever virus, and circulate in high

concentration of virus in its peripheral blood stream (Hughes, 1943). The latter has explained how the lower primates may serve as mobile distributors of virus, especially if the illness produced is not severe, by carrying infection from the host to an area infested with domestic mosquitoes In this manner primates may serve as a link in the chain of events culminating in human infection. It is possible that the palm civet cat *Nandina binotata arborea* may function as a reservoir of virus, the galagos and pottos lemurs are probably of little importance in most areas (Rockefeller Report, 1946)

CHAPTER XLII

PROPERTIES OF THE VIRUS OF YELLOW FEVER

Filtrability

REED and Carroll (1902)[1] and Reed, Carroll, Agramonte, and Lazear (1911) were the first workers to demonstrate that the causal agent of yellow fever was capable of passing through the pores of a Chamberland F filter which were too small for ordinary bacteria to traverse. This finding was soon confirmed by Marchoux, Salimbeni, and Simond (1903) and Rosenau, Parker, Francis, and Beyer (1905). The experiments, however, could be performed only on a limited scale, as the work necessitated the use of a human volunteer on each occasion on which it was desired to test the pathogenicity of a filtrate More extensive filtration experiments were possible after Stokes, Bauer, and Hudson (1928–38) discovered the susceptibility of the *M. rhesus* monkey to infection. After this important observation, Stokes and his colleagues showed that the virus contained in infected monkeys' blood was able to pass the Berkefeld V and N candles as well as the Seitz (E K) asbestos disk filter, at a negative pressure of 400 mm. of mercury. The Berkefeld W candle, on the other hand, retained the agent even when a pressure of 720 mm. was applied Attempts to demonstrate the filtrability of the virus present in infected mosquitoes were also made, but these proved unsuccessful. Apparently, either the agent was not present in a small enough phase in the insect to be filtrable, or else there was insufficient amount to compensate for loss of virus due to adsorption during filtration. Bauer and Mahaffy (1930 *a*) passed the virus through the Berkefeld V, N, and W candles, as well as through the Pasteur-Chamberland L_{11} bougie The presence of serum assisted its filtrability, and the virus survived the pH range 4 8 to 7 8 (Frobisher, 1931 *c*) Kotter and van den Berghe (1935) filtered a 1/1,000 dilution of virulent mouse brain virus through the EK asbestos disk of a Seitz filter.

Size

Findlay and Broom (1933) filtered the virus through graded collodion membranes and found its size to measure from 17 to 28 mμ in diameter. Their work was confirmed later by Bauer and Hughes (1935), who used similar ultrafiltration methods and also concluded that it was exceedingly small in size and measured less than 50 mμ in dimensions The latter investigators also established the point that the size of the virus was not altered as a result of frequent passage through monkeys or intracerebral inoculation of mice For these researches 2 strains of agent were employed, the one called the "Asibi" strain which was originally isolated by Stokes, Bauer, and Hudson in 1927, and subsequently maintained virulent by frequent passage through rhesus monkeys, and the other, a virus isolated by Mathis, Sellards, and Laigret (1928) at Dakar, which had been adapted to mice by Theiler (1930) and had been passaged over 150 times intracerebrally in mice

Preservation of Yellow Fever Virus

Virus could be regularly passaged in monkeys or mice using infected liver or brain tissue respectively for inoculation In the frozen state the material retains its virulence for several months, and Sellards and Hindle used this method for transporting the "French" strain from Senegal to America

Sawyer, Lloyd, and Kitchen (1929) reported that it died out in citrated or clotted blood if kept in a refrigerator, and rarely survived for longer than 35 days

1 References are appended at the conclusion of Ch XLIII, p. 511 et seq

if preserved by this method. It remained active in 50 per cent. glycerol at 0° C. for 100 days, but underwent deterioration thereafter. The most successful method, however, was to desiccate infected blood or liver tissue by drying it from the frozen state *in vacuo*, after which it was preserved for 2 years. Hindle (1929, 1930, 1930 *b*) and Hudson and Klotz (1928) obtained similar results previously (see also Sellards and Hindle, 1928. See also p 504).

Action of Physical and Chemical Agents

Heat.

The virus is destroyed by heating infective material to 65° C. for 10 minutes (Hindle, 1930 *a*), and both neurotropic and viscerotropic varieties of yellow fever virus possess the same degree of resistance to heat (Frobisher, 1933).

Chemical agents.

Both the neurotropic and viscerotropic strains of yellow fever virus appear to be equally susceptible to the action of certain chemical substances. Viscerotropic virus in cell-free serum was inactivated by exposure for 30 minutes at 30° C. to 6 7 per cent. ethyl alcohol and 0 3 per cent. phenol. Tests with eosin, mercuric chloride, and formalin necessitated the use of monkeys as test animals, owing to the toxicity of these substances to mice (Frobisher, 1930, 1933). A dilution of 1/1,000 formaldehyde rapidly kills the virus at room temperature and even at 0° C. its virulence is destroyed in 48 hours It resists a mixture of 60 per cent. glycerol and 0 5 per cent phenol for 5 days at 0° C, but at 16° C. it is killed within 48 hours (Hindle, 1929) Yellow fever virus is not affected by sulfapyridine or sulfathiazole (Koprowski and Lennette 1944 *a*, 1944 *b*).

Photodynamic action of methylene blue.

Findlay (1934 *a*) has demonstrated that both the viscerotropic and neurotropic strains of yellow fever virus may be inactivated by treatment with a 1 in 100,000 dilution of methylene blue, and subsequent exposure to a pointolite source of light for 20 minutes. Virus killed by this method also loses its antigenic properties According to Frobisher (1933), neurotropic yellow fever virus is more resistant to the action of 0 3 per cent methylene blue than the viscerotropic variety.

The effect of acidity and alkalinity.

Hindle and Findlay (1930) showed that viscerotropic virus was destroyed in acid media of pH 3 0 to 4 0 Frobisher (1933) found that the neurotropic virus present in serum suspensions resisted 3 hours' exposure to acidities and alkalinities ranging from pH 5 7 to pH 9 2, but at pH 5.0 it was inactivated after 3 hours (Frobisher, 1931 *b*)

Electrical charge of the virus.

Hindle and Findlay (1930) state that the viscerotropic virus possesses a negative charge between the range pH 5 2 to pH 7.0. The behavior of neurotropic and viscerotropic strains of yellow fever virus when placed in the electric field has been investigated by Frobisher (1933), who found that the neurovirus exhibited 2 broad iso-electric zones, the one in the acid range below pH 6 9 and the other in the alkaline range above pH 7 2 In the case of viscerotropic virus, its iso-electric point was found to occupy the range between pH 6.9 and pH 7 2 The electrical charge of the virus neutralizing antibodies present in yellow fever antiserum has been investigated by Frobisher (1931 *b*) and found to be electronegative at pH 7.4

Adsorption, elution, and purification of yellow fever virus.

Hughes (1934) used the following technique

The brains of 10 infected mice were removed, emulsified in 100 c c. of distilled

water, centrifuged for 30 minutes at high speed, and the supernatant fluid passed through a Berkefeld N filter. To 5 c.c. of the filtrate, 10 c.c. of a glycine-acetate buffer of the desired pH and 5 c.c. of a stock 40 per cent. suspension of kaolin in distilled water were added. The final pH of the mixture was determined electrometrically. The mixtures were allowed to stand at room temperature for 6 hours, then centrifuged, the supernatant fluid being passed through a Berkefeld N filter and tested for the presence of virus The protein content of the filtrate was estimated by Kjeldahl's method and an appropriate correction made for the amount of nitrogen in the buffer. Results showed that the virus is completely adsorbed throughout its range of survival from pH 5.1 to 9.8, but the amount of protein adsorbed decreases with increasing pH values. Thus the virus could be completely adsorbed out of solutions of low protein content (below 0.5 per cent protein) by treatment with 40 per cent. kaolin for 15 minutes.

Elution The optimum concentration of eluent required for liberating the maximum quantity of virus and at the same time releasing the smallest amount of associated protein was also experimentally determined Thus, treatment with N/100 NH_4OH freed 80 per cent. of the original virus content with 3 per cent of the original protein

Resistance to putrefaction.

Bauer (1931) reports that the virus is capable of surviving in the tissues of infected monkeys even if the animals have been dead for a long time, and their organs are in an advanced state of decomposition

Reaction to compression.

The effect of high pressures on yellow fever virus has been studied by Bisset, Nicolau, and Macheboeuf (1935), these workers subjected infective material to 1,000, 2,000, and 3,000 atmospheres of pressure and found that material thus treated, when inoculated into animals, caused death a few days later than usual.

Cultivation of Yellow Fever Virus

Methods similar to those employed by Rivers (1931) and Rivers and Ward (1933) have been used for this purpose by Lloyd, Theiler, and Ricci (1936) and Theiler and Smith (1937) The latter first passaged the "Asibi" strain of virus through 240 subcultures in a medium consisting of minced mouse embryonic tissue and 10 per cent normal monkey serum in Tyrode's solution over a period of 3 years At the end of this period the virus was designated the "17E" strain and was sufficiently attenuated for human prophylactic vaccination

After the 18th passage in the above medium, a separate strain, which was duly named the "17D" strain, was evolved by propagating the virus for 58 subcultures in a medium consisting of minced whole chicken embryo, followed by 160 further passages in chick embryo medium prepared from decerebrated and demyelinated embryos. A 3rd strain of virus was derived from the strain "17E," after its 27th subculture, by propagating it serially 70 times through another medium composed of minced adult mouse testis, followed by 90 further passages in which adult guinea-pig testis was substituted for mouse testis The latter was called the "17AT" strain.

Throughout the whole experiment cultures were incubated at 37° C and subinoculated every 3 to 4 days At each stage cultures were centrifuged, the supernatant fluid tested for infectivity, and a quantity of the material preserved for future use by desiccating it from the frozen state.

Haagen and Theiler (1932) successfully cultivated the virus in tissue cultures consisting of 9- to 10-day-old minced chicken embryos, or else in media prepared from rabbit or guinea-pig kidney or testicle tissue. After 22 passages had been carried out, the culture was tested for pathogenicity and found to produce encephalitis

when injected intracerebrally in a mouse In a subsequent publication Haagen (1933) reported that he was able to maintain yellow fever virus in tissue cultures for more than 100 passages without inducing any change in the properties of the virus The virus was readily neutralized *in vitro* by the addition of immune serum, but once it had entered the tissue cells it was capable of withstanding the action of concentrated immune serum

Infection of mouse embryos *in utero*.

During the course of their experiments, Smith and Theiler (1937) inoculated mouse embryos *in utero* with yellow fever virus. Mice (Swiss strain) were inoculated about the 13th day of pregnancy, 0 02 c c. of virus material being introduced into the uterus with a 26-gage needle through an incision made into the abdominal cavity Four days later the embryos were removed and tested for presence of virus, which appeared in maximum concentration in the brain of the embryo Unmodified strains of virus were also adapted to cultivation *in vitro* in a medium consisting of minced mouse embryo brain tissue in Tyrode's solution containing 10 per cent. monkey serum Later, whole mouse embryo was substituted for the above There was also some evidence to suggest that the neurotropism of the virus for mice could be increased by prolonged cultivation in mouse embryo brain medium Attempts to employ monkey tissues were unsuccessful

Growth of virus in tumor-bearing mice.

Findlay and MacCallum (1937 *b*) grew the virus in the cells of an actively growing mouse carcinoma The tumors were inoculated with a strain of neurotropic virus which was propagated for 50 passages in this manner without loss of pathogenicity. A pantropic strain of virus, which was highly pathogenic for monkeys and hedgehogs, was passaged 65 times through mouse carcinomata and showed considerable loss of virulence, without increase in neurotropism, for these animals after such treatment Findlay and MacCallum also made the interesting observation that yellow fever virus appeared to exhibit a special affinity for neoplastic cells, since it tended to become localized in these tissues following inoculation by subcutaneous or intraperitoneal injection

Cultivation on the chorio-allantoic membrane.

Recent experiments have shown that yellow fever virus may be cultivated in a manner analogous to that of other viruses on this medium Elmendorf and Smith (1937) reported that they were able to propagate unmodified as well as tissue-culture-adapted strains of virus on the developing chicken embryo Altogether 18 subcultures were made, and successive embryos were infected by inoculating them either with the fluid derived from the surface of the chorio-allantoic membrane or else with the minced embryo Similar results have been reported by Jadin (1937)

INSECT VECTORS OF YELLOW FEVER VIRUS

Mosquitoes

The early work of Reed (1902), Reed *et al* (1911), and Marchoux and Simond (1906 *a*) necessitated the use of human volunteers to determine whether insects which had fed on human cases contained the virus or not The experiments answered their purpose for the time being, as they conclusively proved the rôle of *Aedes* as a vector of infection, but were unsatisfactory because the need for human experimental subjects limited the size of tests, and, moreover, the presence of negative results signified nothing, because the individuals used may have been immune to infection

After Stokes and his coworkers discovered the susceptibility of the rhesus

monkey to infection, a great impetus was given to the further study of insect vectors of yellow fever. Table 17 gives a summary of some of the tests which have been carried out with various insects. The general practice of most workers has been to infect the mosquitoes by allowing them to bite a human patient or an infected monkey, or, less frequently, by permitting them to feed on a specially prepared medium containing infected blood. The infected mosquitoes are then tested for the presence of virus by inducing them to bite a normal rhesus monkey. In the event of the insects refusing to feed upon the animal, or the tests being negative, they are then emulsified in saline and injected into the monkey with a hypodermic needle. The results tabulated on p. 489 are by no means comprehensive, but indicate some of the many tests made. Under laboratory conditions, it is apparent that yellow fever can be transmitted by a great many insect vectors other than the principal one, *Aedes aegypti*, but to what extent this occurs in nature is unknown Since Soper (1936) reported that the virus can be transmitted from one monkey to another in the laboratory by mosquitoes of the genus *Haemagogus*, investigations have been resumed afresh from a different angle. Less emphasis has been paid to the search for the existence of simple man-mosquito cycles of infection in urban areas and the pendulum has swung in the direction of a hunt for jungle vertebrate reservoirs of yellow fever and forest mosquito vectors capable of perpetuating the infective cycle in forest zones uninhabited by man. Some of the earlier work on insect vectors may have to be extended in the light of current developments Table 17 contains a record of earlier data.

A summary of previous work on mosquitoes.

The rôle of various species in the propagation of yellow fever is conveniently tabulated in Table 17

BEHAVIOR OF VIRUS IN AEDES AND HAEMAGOGUS MOSQUITOES

The evidence shows that yellow fever virus neither passes through a developmental phase in the mosquito nor does it multiply appreciably in its body. Regarding the first point, work on the growth of yellow fever virus in tissue cultures proves that its passage through the insect vector is not an essential feature of its life history. Secondly, there is no evidence to show that the virus multiplies greatly during the period of its sojourn in the mosquito. Gay and Sellards (1927) measured the infectivity of the virus in insects over a period of 3 weeks, and found that, following an initial increase after feeding, it subsequently remained at a constant level and could be demonstrated in the head, thorax, abdomen, legs, ovaries, salivary glands, and the mid and hind gut of the insect (see also Davis and Shannon, 1930).

Davis, Frobisher, and Lloyd (1933), using Aedes mosquitoes as vectors and rhesus monkeys as test animals, found that the average mosquito, immediately after engorgment, had ingested from 1 to 2 million lethal doses of virus A fortnight later there was a slight decrease in its amount followed by a rise, attributable to an increase of extracellular virus At no time, however, was the quantity of virus titrated equivalent to that demonstrated in the insect immediately after feeding Findings contrary to these have been recorded by Whitman (1937), who titrated the amount of *virus present in A aegypti at different times after infection*, and found that 38 days after it had fed, the titer greatly exceeded the original amount of virus ingested.

At first sight these two statements appear to be conflicting but, as we shall explain, it is quite possible that the virus may multiply greatly in some *Aedes*, whereas in others it may only do so to a lesser extent, and so both workers may be correct According to one explanation advanced by Davis, Frobisher, and Lloyd

(1933), the extrinsic incubation period in the mosquito is the time occupied by the virus in its migration to the salivary glands, and does not represent the interval required for its multiplication Sellards (1935 *a*) has taken the opposite view and maintains that, following a meal of infected blood, much of the virus present in it is destroyed by the tissues of the mosquito, and this would account for the fall in infectivity observed in the days immediately succeeding the intake of blood. The surviving virus then commences to multiply in the mosquito so that, at the end of the incubation period, the bite of the insect proves infective. Sellards points out that the behavior of the virus in the mosquito is analogous to that which is known to occur in the case of protozoal blood parasites, after they have been ingested by certain blood-sucking arthropod vectors If, therefore, Sellards's interpretation were to be accepted, it would explain the divergence of results recorded, since the degree of infectivity of a mosquito at the end of the incubation period is a matter of chance, depending on the extent to which the virus has flourished in the tissues of that particular insect In consequence of these facts, the amount of virus present in the mosquito at the end of the incubation period may or may not exceed the initial quantity it had taken up at the time of the infective meal. Whitman and Antunes (1938 *a*) transmitted 2 strains of yellow fever virus by *Aedes aegypti*, the minimal period between the date of the infectious meal and the earliest ability to transmit infection by biting was 14 to 15 days

Effect of temperature on virus multiplication in *Aedes aegypti*.

The influence of temperature in modifying the length of the extrinsic incubation period of yellow fever virus has been carefully studied by Davis (1932). From these researches it emerged that the duration of the interval period could be shortened by the effect of heat, and lengthened by exposing the insects to cold Davis was able to prove that *Aedes* became infective in as short a time as 4 days if they were kept at 37°C, or else in 5 days at 36°C; 6 days at 31°C; 8 days at 25 1°C., or 11 days at 23 4°C., and took as long as 18 days to acquire infectivity when kept at 18°C. He also demonstrated that, if the mosquitoes were maintained at 18°C. for 30 days, they proved to be noninfective to monkeys, but after the same insects had been reincubated for 6 days at room temperature, they then became infective. In another and similar experiment, *Aedes* which had fed on infected blood were stored at 8°C. for 24 days, at the end of which their bites were shown to be noninfective, but after placing them in warmth for 6 days at 36°C, they became infective. The effect of heat above the optimum temperature requisite for the development of infectivity was also studied by Davis, who found that exposure of mosquitoes to 36°C. for 20 days, followed by 40°C. for 7 hours, appeared to attenuate the pathogenicity of the virus (see also Dinger, *et al.*, 1929 *a*)

Effect of temperature on virus multiplication in *Haemagogus*.

Three-days-old mice inoculated subcutaneously were employed for quantitative assay of virus by Bates and Roca-Garciá (1946 *b*, 1945). Following a large meal, at 20°C, the quantity of virus ingested immediately began to decline and continued to do so until it reached a minimum in 5 days, at which level it remained indefinitely. If the meal was small, infection failed to establish itself in the insect. At 25°C. the lowest level was recorded on the 4th day, and at 30°C. in 2 days. After the minimum titer was attained, virus multiplication progressively increased in amount and adequate virus was present to infect a monkey after 10 days at 30°C, 12 days at 25 to 35° C, and 28 days at 25° C. Mosquitoes became infective after 23 days when incubated at alternate and varying temperatures of 25°C. for 20 hours and 30°C. for 4 hours daily. The temperature range 25° to 35°C. approximated most closely the diurnal fluctuation limits of the forest canopy and appeared to prolong the life of the mosquitoes in addition to encouraging egg laying by the female Much individual variation was noted to occur in the susceptibility of different

Identification of the blood meal in the mosquito.

Some varieties of mosquito feed only on the blood of a single animal, but others feed on a multiplicity of species The type of blood ingested can be identified by means of serological precipitin tests, and from the results it is possible to tell from what kind of animal the mosquito has derived its meal. Davis and Philip (1931) performed precipitin tests for evidence of human hemagglutinins on a range of West African yellow fever vectors, and concluded that *Taeniorhynchus* (*M*) *africanus* and *Anopheles gambiae* fed exclusively upon man, since their stomach contents gave positive reactions only for human cells Likewise, *A. pharoensis*, *A. funestus*, and *Culex thalassius* were also proved to have fed on human blood *C. nebulosus*, a common type of domestic breeding mosquito, was found to contain only chicken blood, but *C. decens*, *C rima*, *T. annetti*, and *Uranotaenia annulata* reacted with both human and avian sera.

POSSIBLE SPREAD OF YELLOW FEVER BY TICKS

Ticks have also been shown to be capable of transmitting yellow fever under-laboratory conditions, and the results of tests conducted on various species are summarized in Table 18 Perhaps one of the most remarkable observations made on this subject has been the report of Aragão (1933), who demonstrated the presence of yellow fever virus in the eggs of *Amblyomma cajennense*, 11 days after being deposited by a female which had fed upon an infected monkey 25 days previously.

Experimental work by Monteiro (1930) suggests that the bedbug *Cimex lectularius* is able to carry the virus for a short period of time

Certain other species of tick are incapable of transmitting yellow fever virus, and Kumm and Frobisher (1932) found that the bedbug *Cimex hemipterus* killed and destroyed the virus after it had ingested infected blood

The ability of dog fleas to transmit yellow fever virus was studied by Hoskins (1934) who reported that *Ctenocephalides canis* (Curtis) did not transmit the virus to monkeys in interrupted feeding experiments, but fleas which had fed on an infected animal 7 hours previously, when injected into rhesus monkeys proved infective Eighteen hours after an infective blood meal the virus was not demonstrable in the bodies of fleas In an interrupted feeding experiment, biting stable flies of the species *Stomoxys calcitrans* (Linn) were also found to harbor the virus for 6 hours, but were unable to transmit it for 16 hours Flies which had fed on monkeys 42 hours previously, when ground up and injected into monkeys, proved to contain the virus, but 48 to 72 hours later the virus disappeared

Haemagogus to infection and length of time required to reach it. Relatively short exposures to high temperatures in nature may greatly hasten virus development. Bates and Roca-Garciá (1945), reported that the extrinsic incubation period of yellow fever virus in *Haemagogus capricornii*, was found to be 22 to 24 days at 24°C. to 27°C., and 13 to 15 days at 30°C. They also mentioned that the habits of the Saimiri monkeys of the Villavicencio area corresponded closely with those of the *Haemagogus* mosquito. See also Bates and Roca-Garciá (1946 *c*).

Contact infection, transovarial passage, feeding with immune sera and other mosquito experiments.

Persistence of yellow fever virus in mosquitoes after death was studied by Wadell (1947), and virus was recovered from *H. equinus* and *H. spegazzinii* from 24 to 72 hours after death. Ether was recommended for killing insects in such tests.

There is no proof that the virus is transmitted from infected to healthy mosquitoes. Aragão (1929) and Kerr and Hayne (1932) state that *occasionally this is possible under laboratory conditions*, but express the opinion that it is *unlikely* that it occurs normally in nature. Hindle (1930) likewise expressed the same opinion and pointed out that, since the male insect did not feed on blood, it probably became infected through surface contact with the feces discharged from infected female mosquitoes, and such superficial contamination could be washed away from the insect's body. The results of Aragão and Costa Lima (1929 *a*, 1929 *b*, 1929 *c*) lend additional support to Hindle's view, since they have demonstrated the existence of *the virus in the dejecta of infected mosquitoes* by inoculating rhesus monkeys with such material. Under experimental conditions it seems possible that the virus can be transmitted by an infected female *Aedes* via eggs to a second generation of mosquitoes. The pioneer investigators, Marchoux and Simond (1906 *a*), suggested that an infected *A. aegypti* could live for 30 days and lay 7 batches of eggs, of which those deposited after the 12 days' extrinsic incubation period became infective 14 days after they had hatched as imagos. It is probable, however, that this does not occur normally in nature, but only under certain laboratory conditions. Davis and Shannon (1930) have investigated the question of the possible spread of yellow fever virus among mosquitoes, and concluded from their studies that it was unable to pass from an infected mosquito through its eggs to a second generation of insects. Further there was no evidence that adult mosquitoes which had been bred from larvae fed on infected mosquitoes could become infective. Whitman and Antunes (1938 *b*) infected half-grown *Aedes aegypti* larvae with a mixture of infected rhesus serum and saline containing 30,000,000 mouse MLD per c.c. Results showed that if unusually large injections such as this were employed the virus of yellow fever could be induced to persist throughout.

Another interesting point investigated in connection with mosquitoes was the experiment conducted by Davis (1931 *a*), who attempted to determine whether *A. aegypti* which had been fed upon the blood of an immune animal would subsequently prove nonreceptive to yellow fever virus contained in infected blood. The tests were negative, for, although the insects were temporarily refractory to infection after being fed on immune blood, after blood became digested *in the* intestinal tract of the mosquitoes, they again acted as carriers of infection.

As mentioned before, personal precautions are necessary for laboratory personnel handling infected mosquitoes, and some of the technical measures adopted for insuring the safety of investigators have been described in a paper by Sellards (1932). This worker has maintained a virulent strain of virus in the laboratory by frequent passage through mosquitoes and monkeys over a period of 3½ years, without accidental *infection*. Laboratory-bred *H. spegazzinii* have been shown to feed readily on brewer's yeast by Bates (1947).

mosquitoes failed to transmit the disease to *Cercopithecus tantalus*, *Cercocebus torquatus*, *Cercopithecus mona*, and *Erythrocebus patas* monkeys, although the blood of these animals gave a negative mouse protection test and contained no yellow fever antibodies. But it was shown that the virus survived in the blood stream of the first 2 named species and these were capable of infecting *A. aegypti*, and, in the case of the 3rd variety, *C. mona*, the blood of the animal proved pathogenic to a rhesus monkey. At the end of the experiment, the sera of all 4 types of monkey were tested again, and now found to have developed neutralizing antibodies for yellow fever virus and were able to confer passive protection on rhesus animals against infection. The existence of inapparent yellow fever infections in monkeys is also referred to by Petit (1929) and Theiler and Hughes (1935). The last-mentioned pair of workers employed the African green monkey of the species *Lasiopyga callitrichus* and observed that if either modified or unmodified strains of yellow fever virus were inoculated intraperitoneally in this variety, the virus multiplied in the blood stream of the animal without giving rise to signs of illness. If, on the other hand, the monkey was injected intracerebrally either with neurotropic or viscerotropic virus, then fatal encephalitis ensued Data are summarized in Table 19.

[1] See footnote to Table 20, p 498

The *M rhesus* monkey is one of the most uniformly susceptible of all varieties, and Bauer (1931) found that the blood of one infected animal was infective to another even up to a dilution of 1 in 1,000,000,000 parts Lewis (1930) also suc-

ROUTES OF INFECTION WITH YELLOW FEVER

The virus appears to be able to pass through unbroken skin, and Low and Fairley (1931) have described 2 cases affecting laboratory assistants in London, one of whom acquired yellow fever through contact with infected blood, while performing a blood count, and the other when conducting a biochemical analysis.

Aragão and Costa-Lima (1929 *a*, 1929 *b*, 1929 *c*) showed that the feces of infected *Aedes* were capable of transmitting the disease to rhesus monkeys, if the material was rubbed into the skin or placed in contact with the surface of the conjunctiva. During the conduct of a postmortem examination on a fatal case of yellow fever, the risk of nonimmune persons developing infection is considerable, and the use of strong rubber gloves is imperative for personal safety.

Direct contact as a possible avenue of infection has been investigated thoroughly by the United States Army Commission, who studied this question during the course of an epidemic which affected Cuba in 1900. As the result of their inquiries they succeeded in proving the noncontagious character of yellow fever infection, and it was shown that cases of the disease could be tended by nonimmune nurses without risk of infection spreading. The same Commission also eliminated fomites as a possible means of conveying infection. Thus, during the progress of an epidemic which affected the members of a military garrison at Pinar del Rio in Cuba, it was revealed that nonimmune persons who had either slept in the beds vacated by the sick, or washed the soiled clothing of dead patients did not contract the disease.

The inability of fomites to transmit infection was convincingly demonstrated in the classical experiments of Dr Cook and other members of the United States Army Commission, who proved that it was possible for a healthy person to sleep for 20 consecutive nights amid bedclothing consisting of pillows, sheets, and blankets which had been deliberately soiled with the black vomit, urine, and feces of yellow fever cases, without becoming infected In one of these experiments two young, susceptible, American volunteers are reported to have slept for 21 nights wearing garments which had been removed from yellow fever patients, in addition to using their much-soiled pillow slips, sheets, and blankets

PATHOGENICITY TO ANIMALS

Chimpanzee

When working at Mañaos, Thomas (1907) reported that he was able to infect a chimpanzee with yellow fever virus Twenty-nine infected specimens of *Aedes aegypti* were permitted to bite the ape, and after an incubation period of 21 days the animal developed a febrile illness which closely resembled that of the human disease

Monkeys

Since Stokes, Bauer, and Hudson (1928) and Mathis, Sellards, and Laigret (1928) discovered the susceptibility of *Macacus rhesus* to experimental infection, other Indian monkeys such as *M sinicus*, *M cynomolgus*, and *M nemestrinus* were likewise found to succumb to inoculation African monkeys, on the other hand, appeared to prove resistant to the virus, and for a time it was thought that such animals owed their freedom from attack to a natural racial immunity. It is now appreciated that this is not true, for many of the African species of animal do not possess a natural immunity, but acquire it at some period of their life in the forest (see Findlay, Stefanopoulo, Davey, and Mahaffy, 1936)

Different species of monkey vary in their susceptibility to infection independent of the presence of serum protective antibodies For example, Bauer and Mahaffy (1930) found that the inoculation of infective rhesus blood and bites of infected

mosquitoes failed to transmit the disease to *Cercopithecus tantalus*, *Cercocebus torquatus*, *Cercopithecus mona*, and *Erythrocebus patas* monkeys, although the blood of these animals gave a negative mouse protection test and contained no yellow fever antibodies But it was shown that the virus survived in the blood stream of the first 2 named species and these were capable of infecting *A. aegypti*, and, in the case of the 3rd variety, *C. mona*, the blood of the animal proved pathogenic to a rhesus monkey. At the end of the experiment, the sera of all 4 types of monkey were tested again, and now found to have developed neutralizing antibodies for yellow fever virus and were able to confer passive protection on rhesus animals against infection. The existence of inapparent yellow fever infections in monkeys is also referred to by Pettit (1929) and Theiler and Hughes (1935). The last-mentioned pair of workers employed the African green monkey of the species *Lasiopyga callitrichus* and observed that if either modified or unmodified strains of yellow fever virus were inoculated intraperitoneally in this variety, the virus multiplied in the blood stream of the animal without giving rise to signs of illness. If, on the other hand, the monkey was injected intracerebrally either with neurotropic or viscerotropic virus, then fatal encephalitis ensued Data are summarized in Table 19

[1] The nomenclature employed in Tables 19 and 20 is not always in accordance with the latest scientific usage, but to avoid dubiety we have adhered to the names employed by the original authors We have also observed that a considerable variation in spelling has been indulged in by different workers describing a single species of monkey sometimes even in the same paper

ceeded in infecting monkeys with as little as 0 000001 c c of infected blood Infection may be produced with human or mouse neurotropic yellow fever virus given by any route of parenteral injection, as well as through the bites of infected mosquitoes, and Findlay and Clarke (1935) showed that, if the virus was instilled into the nose, it could be recovered from the olfactory lobes two days later, after which it became distributed throughout the brain Rhesus monkeys have also been infected with the excreta of infected Aedes mosquitoes by inoculating the material subcutaneously or else by placing it on the surface of the conjunctiva Aragão and Costa Lima (1929 *a*, 1929 *b*, 1929 *c*) have thus drawn attention to the ability of the virus to pass through intact skin and mucous membrane surfaces The incubation

period depends on the dose of virus given and may be as short as 3 or as long as 31 days (Frobisher, 1931 *c*).

If a strain of neurotropic virus be injected subcutaneously or intraperitoneally,

passages were effected, with considerable modification of the properties of the virus (Penna, 1936)

Certain South American species such as *Saimiri sciureus*, *ateleus*, *Cebus frontatus*, *callithrix*, and *Leontocebus ursulus* have also proved susceptible, when inoculated intracerebrally with Berkefeld filtrates of infective tissue (Lloyd and Penna, 1933, and Lloyd and Mahaffy, 1936)

The presence of antibodies in the sera of a proportion of monkeys recovered from an infected area has been studied and Table 20 contains a summary of results

The disease in rhesus monkeys is accompanied by fever, which varies from 104° to 105° F, lasts for 2 days, and frequently results in death During this illness hemorrhagic symptoms similar to those evident in man, such as bleeding from the gums, the characteristic black vomit, and icterus visible in the conjunctivae, are present The urine contains granular and hyaline casts accompanied by albumin and bile The naked-eye and microscopic lesions occurring in experimental yellow fever in the rhesus monkey have been described and compared with the changes produced in man by Hudson (1928, 1928 *a*, 1928 *b*)

With minor differences, the *pathological changes* found in the monkey resemble

are similar to the human appearances, but polymorphonuclear leukocytes and endothelial cells are more numerous In the kidney, congestion of the glomerular vessels and the presence of granular, calcareous, and hyaline casts are less common than in man (Hindle, 1930 *a*) Lesions present in the heart are similar to those found in man and have been described on p. 470

Goodpasture (1932) studied the morbid histology of yellow fever encephalitis in rhesus monkeys after intracerebral injection of virus, and reported that the essential lesion was acute disseminated encephalomyelitis, which extended throughout the brain and caused necrosis of both motor and sensory ganglion cells Intranuclear inclusion bodies were also detected in these cells Findlay and Stern (1935) made similar observations and found that the lesions in monkeys resembled those described by them in mice (see p 500)

The cerebrospinal fluid in infected monkeys has been examined by Mollaret and Stefanopoulo (1934), and, in a few of the animals which had been inoculated subcutaneously with neurotropic virus, the yellow fever virus was recovered from the fluid Eighteen days after inoculation the lymphocyte count rose to 67 2 per c mm and the Pandy test was positive

The regeneration of damaged liver and kidney tissue following recovery from experimentally induced yellow fever has been studied in 6 rhesus monkeys by Klotz and Belt (1930 *b*) On every occasion it was found that the tissue had undergone complete repair without any indication of cirrhosis in the liver, or scarring or contraction of the kidney According to these workers, the absence of fibrosis in the liver and kidney has been ascribed to the peculiar resistance of stroma tissue against injury with yellow fever virus The pathological process is essentially one which is noninflammatory and nonautolytic in character, and which neither gives rise to the formation of thrombi in the small vessels of the parenchyma, nor provokes a connective tissue reaction during the acute phase of the illness The process of regen-

eration takes place quickly and originates from the surviving islands of parenchymal tissue, and from the results obtained in monkeys, Klotz and Belt have concluded that recovery in man likewise pursues the same course.

Chemical and metabolic changes in the infected rhesus monkey have been studied by Wakeman and Morrell (1931). These observers found that the sugar tolerance of the animal was reduced prior to death, and dextrose injected into the blood of monkeys suffering from yellow fever was not as readily removed by the blood stream as was the case when similar amounts were introduced into normal monkeys. Wakeman and Morrell thus demonstrated the loss of hepatic function during yellow fever infection in monkeys The icteric index in rhesus monkeys has been estimated by Kerr (1931), who found that the degree of icterus present on the 2nd and 3rd days of the animal's illness was of diagnostic and prognostic significance For example, if the reading was 10 or more units on the 2nd day, and 15 or over on the 3rd or 4th day of the animal's illness, it usually indicated a fatal termination. The bromsulfalein test was also performed by Kerr (1931), who found the retention of 10 per cent. or more of the dye on the 2nd day of disease, and 15 or greater per cent. on the 3rd day, proved to be a fatal prognostic sign In com- [illegible] to determine [illegible] phenomena [illegible] ttack of the disease derive a lifelong immunity to reinfection. Passive immunity may also be conferred in monkeys by injection of immune serum and Bauer (1931 *a*) points out that this is of long duration if homologous immune serum is employed

Opossums (South American)

Following infection, *Didelphis marsupialis* (common opossum); *D. paraguayensis* (white-eared common opossum) and *Metachirops opossum* (gray-masked opossum) occasionally showed circulating virus in peripheral blood. *M. nudicaudatus* (brown-masked opossum) *Caluromys philander* (woolly opossum), *M cinera*, and *M. incana* (murine opossum) are susceptible (Laemmert, 1946).

Mice

The virus is pathogenic to these animals when injected intracerebrally According to the investigations of Findlay and Stern (1935), neurotropic yellow fever virus, when injected intracerebrally in mice, causes an inflammatory reaction of the central nervous system accompanied by degeneration of nerve cells, the formation of acidophilic intranuclear inclusion bodies, infiltration with mononuclear cells, and proliferation of microglia. Varying stages of degenerative changes were evident in the ganglion cells, such as swelling of the cells, neuronophagia or complete disintegration of their contents Inclusion bodies were seen only in nerve cells which had been extensively damaged, and they failed to stain by the Feulgen technique No evidence of demyelination was observed at any stage of the pathological process (see also Theiler, 1930, and Mathis, 1936) The virus has also been passaged intratesticularly by Lloyd and Mahaffy (1933), and later Smith (1938) carried out 40 passages in this manner When administered by this route it causes slight swelling of the organ, accompanied by an increase in the amount of virus up to the 7th day, after which it declines and disappears completely on the 21st day Smith (1938) reported that yellow fever virus may thus be isolated from infected serum by inoculating mice either intracerebrally or intratesticularly Laigret (1933) employed different strains of mice, namely *Mus musculus*, *M gentilis*, and *M musculus azoricus*, and was able to produce encephalomyelitis in these animals by inoculating them intraperitoneally with neurotropic virus (see also Nicolau, Kopciowska, and Mathis, 1934 *a*, Stefanopoulo, 1934, and Mathis, 1936 *a*) The paths of spread of yellow fever virus in mice have been studied by Findlay and Mahaffy (1936) From their researches they have concluded that the virus, when administered intra-

peritoneally, does not reach the central nervous system centripetally *via* the spinal nerves, but does so via the peripheral circulation, through the nasal mucosa and the olfactory nerves The latter observation is supported by the fact that, when yellow fever virus is introduced intraperitoneally into very young mice, the intranasal instillation of picric acid arrests the spread of infection to the central nervous system Mice have also been infected by instilling neurotropic yellow fever virus into the conjunctival sac of the eye (Findlay and Clarke, 1935).

Guinea-pigs

Theiler (1933) showed that the guinea-pig was susceptible to intracerebral inoculation, and he passaged a strain of neurotropic mouse virus 42 times in this

with a strain of monkey virus were unsuccessful. Immunization of guinea-pigs against neurotropic and 17 D virus by cutaneous scarification has been reported by Favarel (1945).

Hedgehogs

The Sudanese hedgehog (*Atelerix albiventris*) has been successfully infected with viscerotropic yellow fever virus by Findlay, Hewer, and Clarke (1935). Like-

intracerebrally (Smith, 1936) Findlay and Mahaffy (1936), on the other hand, report that the hedgehog *A. albiventris* obtained from Kano in Northern Nigeria was found to be highly resistant to inoculation with neurotropic virus, furthermore, this immunity was not acquired as a result of previous infection, as no antibodies were demonstrable in the blood of one animal examined for this purpose. Two of the animals showed neutralizing properties in their blood after inoculation, and Findlay and Mahaffy concluded that the immunity of the hedgehogs studied by them was a natural and racial characteristic.

The principal pathological changes were seen on microscopic examination of the liver tissue There was fatty degeneration, pigmentation of the Kupffer cells, and diffuse infiltration of the organ with lymphocytes, particularly beneath Glisson's

Bats

The susceptibility of the species *Epomophorous wahlbergi haldemani* (Hallowell) to experimental infection with neurotropic yellow fever virus has been reported by Rodhain (1936) Animals inoculated intracerebrally developed signs of encephalitis in 9 to 10 days, and the virus was thereafter demonstrable in the peripheral blood

Shrews

The Southern Nigerian species (*Crocidura manni*) is apparently resistant to experimental infection with yellow fever virus Smith (1936) showed that although these rodents possessed no protective antibodies in their sera, they nevertheless

could not be infected with a neurotropic strain of virus administered intracerebrally or subcutaneously.

Pigs

Stefanopoulo, Mollaret, and Desnos (1934) showed that the pig was susceptible to intracerebral inoculation with yellow fever virus. Following infection, the animal first showed a rise in temperature reaching 42° C, and later signs of encephalomyelitis, and death in 7 days. Histological sections prepared from the brain of such an animal showed areas of perivascular lymphocytic infiltration or cuffing similar to that caused by other neurotropic virus infections.

Horses

Pettit, Stefanopoulo, and Frasey (1928) found that this animal was resistant to inoculations of yellow fever virus, and after repeated injections the serum of the animal was found to develop antibodies that were able to neutralize yellow fever virus in *in vitro* tests

Young Chickens

These were shown to be susceptible to intracerebral inoculation with the *Asibi* strain of virus which had been maintained in chick embryo tissue for several transfers. One hundred and two direct brain-to-brain transfers were made in chickens Virus appeared in the blood stream on the 6th day and remained in the brain for 14 days. Young chickens never showed signs of encephalitis (Laemmert and Moussatché, 1943).

Birds

In Brazil, Laemmert, de Castro-Ferreira, and Taylor (1946) shot 141 birds representing 45 species and examined the livers for evidence of yellow fever virus but with negative results throughout

Poikilothermal Animals

The following creatures captured in the vicinity of Villavicencio, Colombia, could not be infected with yellow fever virus by Laemmert (1943). The iguanas, *Iguana iguana* (L.), the lizard, *Tupinambis nigropunctatus* (Spix) tortoises, *Testudo tabulata*, Walbium, boas, *Constrictor c constrictor* (L), toads, *Bufo marinus* (L); and tree frogs, *Hyla sp* Likewise, negative were lizards, *Tupinambis teguixin* (L) and frogs, *Leptodactylus ocellatus* (L) gathered from near Rio de Janeiro

Other Animals

The cat, rabbit, rat, ferret, golden hamster (*Cricetus auratus*), wood vole (*Apodemus sylvaticus*), bank vole (*Evotomys glareolus*), pigeon, hen, and canary are resistant to intracerebral inoculation with a strain of neurotropic yellow fever virus There is no evidence, however, that the virus can multiply in these animals and no histological changes have been demonstrated in their brains (Findlay, 1934 *a*).

The red squirrel (*Sciurus vulgaris*) and the field vole (*Microtus agrestis*) are susceptible to intracerebral inoculation with neurotropic virus Findlay (1934 *a*) observed that in the field vole, infiltration of the meninges, perivascular cuffing, and degeneration of ganglion cells were present, but to a lesser extent than in mice

CHAPTER XLIII

IMMUNITY MECHANISMS IN YELLOW FEVER

PROPHYLACTIC IMMUNIZATION

THE EMPLOYMENT of killed virus has given disappointing results in animal experiments and consequently it has been rejected for human inoculation Attention has therefore turned toward devising ways and means of cultivating yellow fever virus such as, for example, by repeated intracerebral passage through mice or prolonged growth in tissue culture, with the object of inducing the agent to acquire fixed affinities for particular types of tissue Thus, a strain of modified virus was derived which was sufficiently attenuated in virulence to render it safe for human administration

Since living virus is essential for production of high-grade immunity it is probable that, before antibodies can develop in the serum of a nonimmune subject, the individual must first pass through a subclinical phase of the infection. With the use of live vaccines there is an ever present risk of the virus reverting to its pathogenic properties, but fortunately the occurrence of such incidents has been rare.

Prophylactic vaccination has been evolved from studies originally directed towards insuring the personal safety of investigators engaged in yellow fever research Thus Sawyer, Kitchen, and Lloyd (1932) inoculated a number of workers with fixed mouse virus along with immune human serum, and the efficacy of the procedure was immediately apparent as it terminated the long series of laboratory infections which hitherto had been experienced (see Berry and Kitchen, 1931). Findlay (1934) employed this same method of immunization for 200 cases, and as far as can be determined there are no grounds to suspect that such vaccination has failed to protect persons against an attack of the disease (see also Laigret, Saleun, and Ceccaldi, 1937, Sellards, 1937, Findlay, 1937, and Sellards and Laigret, 1936) From the practical standpoint this method was unsuitable for human inoculation on a large scale, since it necessitated the use of large amounts of immune human serum and, moreover, it was unsafe to administer the virus alone, owing to the possible danger of reversion to its pantropic characteristics For further information on the subject of yellow fever immunization the reader is referred to the writings of Findlay (193[illegible]), Findlay and MacCallum (1937 c), Haagen (1937), [illegible] (193[illegible])

Theiler (1937) showed that the continued propagation of yellow fever virus in tissue cultures led to great modification in invasive properties, so that ultimately it became safe for human immunization See Lloyd, Theiler, and Ricci (1936) and Theiler and Smith (1937)

Cultivation of 17D Strain

The rhesus monkey adapted *Asibi* strain of virus (Lloyd, Theiler, and Ricci, 1936) was passaged by Theiler and Smith (1937) through 18 subcultures in minced chick embryo tissue containing 10 per cent normal monkey serum in Tyrode's solution After the 18th subcultivation, virus was grown for 58 passages in a medium of whole chicken embryo followed by 160 further transfers in medium composed of decerebrated and demyelinated embryos. The resulting virus designated 17D was found to be much reduced in neurotropism and viscerotropism and to be capable

of protecting monkeys against virulent virus. It was also safe enough for human prophylactic inoculation and in November, 1936, Theiler and Smith (1937) inoculated 8 human volunteers with modified 17D virus without the addition of immune human serum, 17D virus could not be transmitted by *Aedes* and the quantity of circulating virus in vaccinated persons was too small to be transmitted by *Aedes* (Whitman, 1939).

The growth characteristics of 17D strain yellow fever virus in cultures of embryonic chick cells in Tyrode's solution has been studied by Fox (1947). The concentration of virus in tissue was found to be 100 times that present in supernatant. The maximum phase of virus multiplication coincided with the greatest period of tissue activity in the culture, namely the first 3 days. By progressively lowering the temperature of incubation from 39.5° C. to 27° C. the peak was delayed until the 8th day. The effects of reduced oxygen tension and size of inoculum also affected virus multiplication Cultures could be prepared and stored in advance at 5° C for 51 days before inoculation without impairment of efficiency. Fox and Laemmert (1947) were also able to cultivate 17D strain virus on 7 to 8 days old embryos by inoculation of dropped chorio-allantoic membrane. Virus first proliferated at the site of infection later invaded the blood stream and thereafter became localized and multiplied in the embryo, particularly in muscle and brain. The presence of sulfapyridine and sulfathiazole in tissue cultures did not interfere with the multiplication of 17D high substrain yellow fever virus (Koprowski and Lennette, 1944 *a*).

Preparation and Assay of 17D Vaccine

According to Smith, Penna, and Paoliello (1938) virus previously cultivated 205 to 287 times in embryos was inoculated in 7-day-old chicken embryos, into the embryo itself, incubated at 37° C. for 3 days and the embryos harvested. Pooled embryos were thereafter triturated in a mortar with abrasive; a 10 per cent. suspension prepared with normal undiluted or 1.50 diluted human serum (now omitted, see Sawyer *et al*, 1944), clarified with coarse filtration, later through a Seitz EK filter; put up in ampules, frozen in alcohol and CO_2 snow, desiccated *in vacuo;* tested for sterility, and stored at 4° C. until required for use. Biological assay of potency and freedom from excessive neurotropism and viscerotropism are determined by intracerebral inoculation of a monkey with 1 c c. Also serial dilutions are inoculated intracerebrally in mice from which the 50 per cent end point activity titer of virus is calculated. The influence of prolonged propagation of the Asibi strain of yellow fever virus in minced chick embryo Tyrode medium was investigated by Bugher and Smith (1944) No difference could be detected in the antigenicity of vaccine lots prepared from material ranging from 212 to 450 serial egg passages Fifty-seven subcultures of 17D strain virus in the presence of specific yellow fever antibody failed to modify its antigenicity in man, as measured by the intraperitoneal mouse protection test. Virus dosage of 10 MLD (50 per cent mortality probability in mice) gave an irregular immunization response in man One hundred LD50 dose was found to be the safe minimum for human inoculation According to Fox, Kossobudzki, and Fonseca da Cunha (1943) the routine vaccinating dose should contain not less than 500 MLD (LD_{50}) for mice (See also de Paula Souza, 1945.)

Storage.

According to Barruss and Hargett (1947), desiccated 17D yellow fever vaccine retains its potency for 3 years at −9° C to −32° C, and 2 years at −5° C to −25° C At 37° C., some 90 to 99 per cent virus activity was lost in 2 to 8 weeks Diluted vaccine ready for inoculation should be shielded from excessive light and heat and be used 1 hour after preparation Should it be necessary to employ vaccine of questionable potency then 10 to 20 times the usual dose should be administered.

Route of inoculation.

The antigenic response in man is most active following intradermal inoculation, and less so by the intramuscular and subcutaneous routes. Provided that an adequate volume is administered, subcutaneous inoculation suffices for practical purposes.

Efficacy of 17D vaccine.

The value of this safe method of immunization in man is now universally recognized. Its introduction among members of the staff of the International Health Division of the Rockefeller Foundation and Special Study sections in Colombia have abolished laboratory infections among workers exposed to intimate contact with virus in the laboratory and field. In the field, Bugher and Gast-Galvis (1944) reported only 1 case of yellow fever among 600,000 persons vaccinated with 17D virus whereas in Colombia for the same period 345 proved and 254 probable infections occurred among unvaccinated persons.

Duration of human immunity following 17D vaccination.

This has been stated to be at least 5 years and probably much longer (Anderson and Gast-Galvis, 1947). Antibodies appear 7 to 10 days after inoculation and last at least 3 years according to Smithburn and Mahaffey (1945). According to Fox and Cabral (1943), among a group of adults inoculated with 17D vaccine 4 years previously, only 2 per cent. failed to show protective response. Similar tests among young individuals showed that after a lapse of 2 and 3 years, nearly 10 per cent. failed to exhibit immunity and a well-marked correlation existed between age and antibody level, the lowest being returned in the case of children under 10 years of age.

Failure of 17D vaccine to protect.

It has been observed that sometimes certain individuals fail to respond to such immunization. The prophylactic value of 17D vaccine was put to a severe test from 1939 to 1945 when thousands of inoculated British and other troops were exposed to infection in the West and other parts of Africa. Elliott (1944) has recorded 3 histologically proved, fatal cases of yellow fever affecting military personnel in West Africa who had been inoculated 2 years previously.

Post Yellow Fever Vaccine Jaundice

Findlay and MacCallum (1937 *a*) first reported that 2 to 3 per cent. of 2,200 persons receiving yellow fever vaccine developed jaundice 2 to 7 months later. They stated that jaundice was not due to infection with yellow fever virus but some other cause, an observation which has since been confirmed, and jaundice is now known to be caused by contamination with the virus of human serum jaundice.

In 1939, jaundice appeared in some 27 per cent. of 304 persons who had been vaccinated with Lot 467 of 17D tissue culture yellow fever vaccine which contained normal human serum in the fluid component of the tissue cultures in which the source of virus was propagated. A further group of 1072 cases of jaundice developed in 1940–41 among 19,000 persons vaccinated in S.E. Espirito Santo. In the light of present knowledge it is certain that the portal of entry of the icterogenic agent was human serum and that Seitz filtration with heating to 56° C. for 30 minutes was inadequate to inactivate the virus of serum jaundice. Later batches of vaccine were prepared without the addition of human serum and no further cases have since occurred (Fox, Manso, Penna, and Madureira-Pará, 1942).

An extensive account of post yellow fever jaundice is given by Sawyer, Meyer, Eaton, Bauer, Putnam, and Schwentker (1944). The incubation period was found to be 60 to 150 days and the highest mortality 3 per 1,000 cases. These workers recommended that serum-free yellow fever virus should be used for immunization

Encephalitis after Yellow Fever Vaccination

Signs of central nervous system involvement following yellow fever immunization have been reported frequently in the literature. Fortunately, the percentage of individuals who develop these unpleasant reactions is very small, and the prospect of encountering such symptoms after inoculation should not be accepted as a valid excuse for refusing prophylactic immunization. For an account of various nervous reactions following anti-yellow-fever vaccination the reader is referred to the work of Barraux, Montel, and Bordeo (1936), Laigret (1936), Darre and Mollaret (1936), Mollaret and Findlay (1936), Lhermitte and Freibourg-Blanc (1936), and Peyre and Fricaud (1937).

Although reports from various quarters have indicated that mouse brain virus can be used with safety for human immunization against yellow fever, the recent work of Findlay and MacCallum (1938) has revealed that even though it may be possible to obtain a neurotropic strain of yellow fever virus for mice, such neurotropism may be confined to the mouse alone and not apply, for example, to the monkey. Thus, it was shown by these workers that even after a strain of virus had been passaged 670 times through the brains of mice, when inoculated into monkeys it produced death with viscerotropic lesions. The liability of yellow fever virus to undergo spontaneous change in its affinities for different tissues is, therefore, a property which must be remembered, and Findlay and MacCallum accordingly have advocated that all strains of virus employed for human immunization should be tested periodically for pathogenicity to insure that no alteration in characters has occurred.

Fox, Lennette, Manso, and Souza-Aguiar (1943) reported that a single substrain of 17D virus was observed to undergo "variation" with the result that of 55,073 persons vaccinated in the arm, 199 of these (0.50 per cent.) presented evidence of central nervous system involvement, with 1 fatality

Allergy to Egg Protein

Two severe cases have been reported by Sprague and Barnard (1945) but mild reactions are not infrequent Individuals susceptible to asthma, urticaria and other allergic phenomena are likely to develop massive edema, dyspnea and dysphagia following parenteral inoculation of egg protein

Use of live neurotropic mouse brain adapted virus (Dakar vaccine).

Sawyer (1937) and Sawyer, Kitchen, and Lloyd (1932) employed mouse brain adapted yellow fever virus combined with immune human or monkey serum Owing to the inconvenience of obtaining adequate amounts of the latter for large scale vaccine production, the method was discontinued Sellards and Laigret (1936) vaccinated humans with similar virus devoid of immune serum but because of undesirable neurotropic effects and adverse reports by Findlay (1934 *b*), Theiler and Whitman (1935 *b*) doubt was cast on the advisability of its continuation The experiences of French workers are summarized by Mathis (1938) and Stefanopoulo (1937). At the time of writing, the latest method of preparation and inoculation practiced at the Pasteur Institute, Dakar, consists of the application of neurotropic mouse brain virus by scarification and in a suspension of gum arabic

Comparative value of Dakar mouse brain and 17D chick embryo yellow fever vaccine.

Tests were conducted under the auspices of UNRRA with the following findings Neurotropic mouse brain live yellow fever virus supplied by the Pasteur Institute, Dakar was tested and found to have an intracerebral mouse infection potency of 10,422 LD50 per c c Virus was suspended in gum arabic, frequently combined with vaccinia virus and administered by scarification to 2 groups of 200

French soldiers each. Group A received neurotropic mouse brain vaccine in gum arabic by scarification, Group B received similar virus to which was added anti-smallpox vaccinia virus vaccine

A 3rd group of men was inoculated with 17D egg embryo virus, the infective titer of which was 49,506 LD50 per c c. Results of immunity tests showed that of Group A, 96.88 per cent. developed neutralizing antibodies, Group B showed 97 47 per cent. and Group C, who received 17D virus, showed 55 60 per cent. positive sera by the intracerebral mouse protection test, and 97–100 per cent. by the intraperitoneal test. de Paula Souza (1946), therefore, concluded that "under the conditions of the experiment the highly neurotropic Dakar vaccine, when inoculated by scarification of the skin, gave a higher degree of immunity, as expressed in the amount of protective antibody produced in their blood, than did less neurotropic 17D virus when injected subcutaneously. There were thus two important variables and the experiment as set up could not show the separate effects of the type of virus and the method of inoculation"

It is interesting to note that although 17D egg embryo virus contained almost 5 times as many LD50 doses as Dakar vaccine in man, the immunological response of the former was much less than the latter Over 14,500,000 persons have been inoculated in the French colonies with the Dakar vaccine.

For obvious reasons 17D has much to commend its use since it is less liable to become contaminated with extraneous live viruses which may gain access to mouse brain tissue

Egg Yolk and Olive Oil Treated Vaccines

In the past, virus coated with a film of olive oil and egg yolk has been tried, and a single dose equivalent to 320 M I D for mice administered. Nicolle and Laigret (1935) inoculated 10,000 persons by this method, and recorded only 2 non-fatal cases of meningitis with 1 of myelitis (see also Nicolle and Laigret, 1936, and Laigret and Durand, 1936) A modification of the former employing egg yolk was described by Mathis, Durieux, and Mathis (1936)

Experiences Reported with Killed Virus

Findlay (1934) found that virus inactivated by the photodynamic action of
and Hughes (1936)
killed by exposure
the administration
l to the course of
injections.

ANIMAL PROTECTION TESTS

The development of antibodies in the serum of a human subject or a monkey after an attack of yellow fever has long been recognized (Stokes, Bauer, and Hudson, 1928) and convalescent serum has been shown to exert powerful *in vivo* and *in vitro* neutralizing effects upon yellow fever virus Stokes and his colleagues found that even as little as 0 1 c c of convalescent human serum was sufficient to protect a monkey against a simultaneous dose of live virus This important discovery has been utilized by later workers to form the basis of biological tests for the detection of neutralizing antibodies in human, monkey, and other varieties of mammalian sera Monkey protection tests were, however, unsatisfactory for the reason that the cost of the animals prohibited their employment in extensive field investigations, and it was not until 1930 that the researches of Theiler (1930) led the way to a further possibility in the study of protection tests Theiler showed that yellow fever virus, provided it was inoculated intracerebrally, was pathogenic to the white mouse. He proved further that the repeated intracerebral passage of the virus in mice led to its adaptation for the central nervous system, so that ulti-

mately a strain of virus was derived exhibiting a fixed neurotropism for mice, following its being administered by any route.

The Intracerebral Mouse Protection Test

Using neurotropic mouse virus, Theiler (1930) showed that the existence of protective antibodies in human sera could be demonstrated by inoculating a mouse intracerebrally with a mixture consisting of virus and antiserum. Notwithstanding the effect of immune serum, and the smallness of the dose of virus (a 1 per cent. suspension of brain), the test was not delicate enough as there was a tendency for the mice to succumb at too irregular intervals. When using this procedure, the animals usually died in from 5 to 16 days after inoculation, and the results left much to be desired. The problem was reinvestigated by Sawyer and Lloyd (1931) with the aim of making the test more delicate in operation, and after a series of experiments these workers succeeded in evolving the method next described.

The Intraperitoneal Mouse Protection Test

This test differs from Theiler's test since it utilizes the employment of another principle in its operation. Instead of introducing the mixture of virus and serum intracerebrally in a mouse, the animal is first injected intracerebrally with starch and thereafter intraperitoneally with a mixture of virus and serum to be tested. The action of the starch causes cerebral trauma which damages the blood brain barrier (see Friedemann and Elkeles, 1934) so that the virus can leave the circulation and freely invade the injured nerve cells. The time taken by the virus to reach the central nervous system from the general circulation proves an additional advantage as it affords ample opportunity for neutralization of the virus to occur—if antibodies are present—and at the same time it delays death of the mice by about 2 days. In consequence of this, if the serum injected possesses no neutralizing antibodies for yellow fever virus, the majority of mice succumb between the 7th and 11th days following inoculation. It has been mentioned that in performing the mouse protection test the virus-serum mixture has to be introduced intraperitoneally, and the necessity for employing this route of inoculation has been experimentally demonstrated by Sellards (1935 *a*), who showed that, although the brain of an animal was traumatized and massive doses of virus were administered subcutaneously, it failed to develop encephalitis. The tendency of the virus to enter the blood stream and brain is considerably greater when the material is injected intraperitoneally than by the subcutaneous route. A point worthy of mention is the fact that different strains of white mice are sometimes liable to vary in their susceptibility to yellow fever virus, and, accordingly, a suitable strain must first be procured for the purpose.

The value of the mouse protection test for yellow fever, the uniformity of its results, and the specificity of its response have now been universally accepted and accorded world-wide recognition.

Technique. The test is carried out according to the following method (Sawyer, 1931).

A mouse is injected intracerebrally with 0.03 c.c. of a solution consisting of 2 per cent. starch made up in 0.9 per cent. sodium chloride. Simultaneously, the animal is given an intraperitoneal inoculation of 0.2 c.c. of a 20 per cent. saline suspension of virus contained in mouse brain tissue, mixed with 0.4 c.c. of the specimen of serum being tested. Six mice are inoculated with each sample of serum and kept in a glass jar under observation for a period of 14 days. Each series of tests is controlled by including a known positive serum derived from a recovered human case of yellow fever, as well as a negative serum obtained from a person resident in a non-yellow fever country.

Before *interpreting the results*, death of all the 6 mice should occur in the case of the negative control serum not containing neutralizing antibodies for yellow

fever virus With the positive control, complete protection should result and all the mice should survive. Provided that the above controls are satisfactory, the results of the test serum may next be interpreted If all the mice remain alive, it can be assumed that the individual from whom the serum has been derived possesses antibodies for the virus and has, therefore, suffered from infection during the past. If, on the other hand, all 6 mice succumb to infection, then it can be concluded that the individual in question has never been infected with yellow fever virus during his or her life. It can also be argued that such nonimmune persons are likely to develop the disease in the
mediate to the above are ir
mice surviving, the greater
blood. Mahaffy, Lloyd, and
ards for the interpretation of results

TABLE 21

Number of Mice Surviving 10 Days after Inoculation	*Number of Mice Alive 4 Days after Inoculation*	*Interpretation of Ratio*
6	6	Positive
5	6	Positive
4	6	Inconclusive
3	6	Inconclusive
2	6	Negative
1	6	Negative
0	6	Negative
5	5	Positive
4	5	Positive
3	5	Inconclusive
2	5	Inconclusive
1	5	Negative
0	5	Negative
4	4	Positive
0	4	Negative

With less than 4 mice surviving on the 4th day the test is unsatisfactory (Whitman, 1943). A technique for testing small quantities of serum has been evolved by Lloyd and Mahaffy (1935).

The procedure requires only 0.3 c c of serum, and 2 animals can be injected intracerebrally with the serum-virus mixture. The method is said to give 95 per cent correct results

In Uganda the test employed by Smithburn (1945) utilizes 5–6 weeks old mice. A minimum of 0 3 c c of serum is necessary for the test. Groups of 6 mice each receive an intracerebral dose of 2 per cent. starch, and immediately afterwards an intraperitoneal dose of 0 6 c c of a mixture of 0 3 c c serum and 1.5 c.c. of 1 per cent. virus without preliminary incubation A procedure employing less than 0 3 c c of serum is also described If not more than one mouse dies the serum is assumed to contain protective antibodies. Should 2 or more mice survive serum is presumed to contain antibodies Death of one or more mice, or survival of more than 2, signifies an inconclusive result.

Intraperitoneal Test in Young Mice without Starch

The extreme susceptibility of very young mice to extraneural injection was shown by Theiler (1930) and Bugher (1941). Whitman (1943) devised a test employing 18 to 21 days old Swiss mice, some features of which are as follows The 50 per cent. end point of virus infectivity by the intraperitoneal route was accepted as 1 MLD and any immune serum providing complete protection against this dose was regarded as having a titer of 1 For example, it was observed that 0 02 c c. of 15 per cent mouse brain injected intraperitoneally in 21 days old mice had a titer of 10 MLD in that when diluted 1 10 it killed 50 per cent. of mice (Reed

and Muench, 1938). When the same material was titrated intracerebrally it contained more than one million MLD. When 2 parts of immune serum are added to 1 part of virus, the results of injecting 0.06 c c of the mixture into 18 to 21 day old mice are equivalent to injecting adult mice which have received intracerebral starch with 0 6 c c. This permits satsifactory tests in much smaller samples than required for the standard test For details of technique and dilutions used see Whitman (1943). At the end of 10 days the results are interpreted in the same manner as the standard test. Small amounts of antibodies are said to be detectable by this method. See also Loring for tests using young mice.

Specificity of Yellow Fever Virus Neutralizing Antibodies

Although a high degree of specificity is observed in the serological response following natural or artificially induced immunization against yellow fever virus in man, monkeys, and related primates, the same does not hold true for the cow, sheep, goat, dog, and other species. Koprowski (1946) adds that sera derived from the latter in Brazil also exhibited nonspecific neutralization against such a wide range of viruses as those of Japanese B encephalitis, St. Louis encephalitis, and West Nile virus, all of which presumably did not occur in Brazil. Furthermore, such antibodies could not be annulled by heating at 56° C

Natural Neutralizing Antibodies in Babies

Soper, Beeuwkes, Davis, and Kerr (1938) found that the presence of yellow fever antibodies in the sera of infants at birth was related to the antibody content of their mothers. Moreover, such immunity was fleeting in character and disappeared within the first few months of life.

Complement Fixing Reactions

The existence of specific complement fixing antibodies in the sera of human beings, and also in monkeys who have recovered from an attack of the disease, has been described by Moses (1929), Frobisher (1930, 1931, 1931 *a*, 1933), and Davis (1931 *a*) The method of preparing antigen and the technique of setting up the test is described on p. 104.

Antigens suitable for the test.

Frobisher (1931) reported satisfactory results using antigen extracted from the liver of infected monkeys by the use of isotonic and hypertonic salt solutions, combined with the application of alternate freezing and thawing. Saline extracts of monkey liver tissue tended to become anticomplemenatry when stored in cotton-stoppered flasks, therefore hermetically sealed ampules were essential Likewise, the addition of eosin or alcohol gave rise to similar anticomplementary properties The antigen was found to be destroyed by heating it to 55° C. for half an hour The addition of alcohol and alcoholic solution of cholesterin caused undue precipitation when added to the liver antigen, and the use of lipoids as sensitizing agents also was not to be recommended Either fresh liver tissue or that which had been desiccated *in vacuo* was found to react satisfactorily, although better results were obtained from the use of fresh liver Neurotropic strains of virus have also been found to act as efficient antigens, and in some cases virus contained in mouse brain tissue provided superior results to viscerotropic virus (Frobisher, 1933)

Other infective materials found to possess antigenic properties were monkey blood removed from the animal during the early stages of its illness, and also Berkefeld filtrates prepared from saline extracts made from infective mosquitoes, both of which reacted strongly in the presence of immune monkey serum In another paper, Frobisher (1931 *d*) reported that antigen prepared from the liver tissue of rhesus monkeys which had been freed from fat by treating the material in a Soxhlet extraction apparatus yielded results superior to that obtainable by any

other method. The use of such antigen for the complement fixation test is described on p 107.

Results. From his experiments Davis (1931) showed that the sera of monkeys which had recovered from yellow fever developed complement fixing antibodies No antibodies could be detected in the sera of normal monkeys or those which had been injected with dead virus, or passively immunized with monkey or human antiserum. The interesting point was also established that, in the case of monkeys which had survived an attack of yellow fever, after a lapse of time, when comple-

months later the test was still positive, although less pronounced, and a smaller amount of complement united From the results of their studies in Brazil, Soper and de Andrade (1933) concluded that a close correlation existed between the results of the complement fixation reaction, the mouse protection test, and the history of recent illness. Davis (1931) considered that the results of the complement fixation te low fever

man and monkeys

fo 17D virus has been

reported by Lennette and Perlowagora (1943) The latter mentions that since complement fixing antibodies disappear rapidly following infection, their presence in sera should be accepted as indicative of recent infection and as such should claim a place in immunity surveys when it is desired to ascertain the duration of infection. The test may also be of value in the early diagnosis of yellow fever (Perlowagora and Lennette, 1944)

The Precipitin Reaction

The technique of the test is described on p 103 During an acute attack of yellow fever in the monkey, a substance appears which can be precipitated from serum by treatment with the serum of an animal which has already recovered from the disease. This observation has been extended to human beings, and Hughes (1934) showed that the serum of a recovered patient contained a precipitin which reacted with precipitinogen reported in the blood of infected monkeys. This precipitinogen is not the virus of yellow fever, but is associated with the albumin fraction of the serum protein, and its amount in the circulating blood increases with the severity of the infection and declines with recovery (Hughes, 1934) It is possible that the presence of this substance in the sera of human cases of yellow fever may conceivably be of value as a laboratory aid to the clinical diagnosis and prognosis of the condition In discussing the relationship of the precipitin reaction to the complement fixation test, Hughes points out that parallel tests on monkeys have proved that in no case has a positive precipitin result been obtained without a simultaneous positive complement fixation response He adds that only 3 sera examined by him showed positive fixation of complement, without the simultaneous or preceding occurrence of precipitins The 2 phenomena, therefore, appear to be intimately related to one another in yellow fever

On the shores of the Adriatic. The disease occurs in Dalmatia, Herzegovina, at the tributaries of the river Po, and Istria (see Gabbi, 1915 *a*, and Peschle, 1936).

In the Mediterranean area. It is commonly seen in Athens (Alivisatos, 1936), Malta (Whittingham and Rook, 1923 *a*), Haifa (Schapira, 1926), Sicily and Calabria (Gabbi, 1915 *a*), Corsica (Leger and Séguinaud, 1912), Jerusalem (Muhlens, 1912), as well as along the northern shores of Africa and Egypt (Sergent, 1914). It is being increasingly recognized in S France, e g, in Marseilles (Genevray, 1946), and Montpellier (Janbon, Harant, and Chaptal, 1942). It presented a definite military problem during the Second World War, incapacitating large numbers of men for up to 2 weeks (see, e g, Cullinan and Whittaker, 1943; Sabin, Philip, and Paul, 1944, Fleming, Bignall, and Blades, 1947).

Africa In Kenya cases have been observed by Jewell and Kauntze (1932), and at Dar-es-Salaam by Manteufel (1912).

In the Far East. The disease has been observed in China at Peking, Tientsin, and Hong Kong (Yang, 1934, Bolt, 1944).

South America. Cogollo Duque (1935) reported the outbreak of a disease resembling sandfly fever at Bolivar, Colombia

The Effect of Temperature on Seasonal Incidence

In India, the peak of the sandfly fever epidemic usually occurs in the spring of the year about May or April If, however, the temperature remains low, owing to the presence of late winter rains, then the onset of the epidemic is delayed until June, and this fact has been experimentally proved by Whittingham (1924), who showed that infected sandflies failed to transmit the disease to human volunteers when the temperature fell to 54° F. The early advent of warm weather in the spring, on the other hand, accelerates the onset of an outbreak.

Some Biological Characters of the Sandfly

In size the insects are about the dimensions of a pin's head (see Theodor, 1938). They breed among the cracks and crevices of walls, parapets, artificial embankments, and amid the rocks and stones of dried-up river-beds Gabbi (1915 *b*) states that in the volcanic districts of southern Italy old deposits of lava provide favorable conditions for their existence. The insects pass the winter months in the larval stage and breeding is encouraged by darkness, moisture, and traces of organic matter (see Smith, Mukerjee, and Lal, 1936). Favorite breeding sites for sandflies are the cracks and crevices found in the walls of dilapidated latrines Breeding also occurs in the boles of tree trunks, in consequence of which Gabbi (1915 *a*) has suggested that they may be transported from one place to another by sailing vessels. During the hot weather season, the insects assume their adult form and move from place to place by means of a series of short flights of about 50 yards each, and seldom at

... as they observed it during the summer months in Malta, occupied a period of about 8 weeks, depending upon the temperature, food supply, and humidity. The egg stage occupied 9 days, the larval stage 28, the pupal stage 10, and the imaginal stage 14 days Each phase of the life cycle of *P. papatasii* was shown to be governed by climatic conditions, the insect hibernated when the earth temperature fell below 65° F.; the optimum required for hatching of the imago was 70° to 90° F, and excessive moisture proved injurious to all stages of the developing insect Whittingham (1924) also found that the female of *P. papatasii* lived from 10 to 14 days, during which some fed daily, but others only at intervals of 3 to 4 days The time taken by an unfed fly to ingest a meal was about 2 minutes, and 5 to 10 minutes for one which had previously had a meal Wenyon (1913) induced

CHAPTER XLIV

SANDFLY FEVER

Synonyms

PAPPATACI fever, Phlebotomus fever, Three-day fever, Chitral fever, Summer fever, Mediterranean dengue, Simple continued fever, Heat apoplexy, *Influenza malarica*, "Dog disease," *Hundskrankheit*, *Sommerfieber*, *Sommerinfluenza*, *Soldatenfieber*, *Endemischer Magencatarrh*, *Febbre dei tre giorni*, *Mal della Secca*, *Febbre estiva*, *Gastroenteritis endemica*, *Gastroenteritis climatica*, and *Febbre da canape* (see Doerr and Russ, 1914).

Historical

The disease has existed for many years in Italy, where it has been known by different names Pick (1886) is credited with having been the first observer to describe the condition as a clinical entity, and Taussig (1905) as having first recognized its association with *Phlebotomus papatasii*. Although the disease is popularly referred to by English-speaking people as "sandfly fever," Newstead (1911) points out that as the pappataci flies belong to the genus *Phlebotomus*, this term is a misnomer and that the designation "phlebotomus fever" is more correct.

During the course of an epidemic among soldiers in Herzegovina, the malady received the attention of the Austrian military physicians, and in 1908 the commission consisting of Doerr, Franz, and Taussig (1909 *a*, *b*) proved it to be a virus infection transmitted by the sandfly, *Phlebotomus papatasii* (see also Doerr, 1910, 1911). The work of Doerr and his colleagues was soon confirmed by Birt (1910 *a*) and others, who proved that the etiological agent was a filter-passing virus Later Whittingham (1922, 1924) and Couvy (1922) isolated leptospira from suspected cases of sandfly fever, and for a time it was believed that the disease was caused by a spirochete and not a virus Following the researches of Kligler and Ashner (1928) in Palestine, it was clearly shown that leptospira could not be demonstrated in infected human blood or in sandflies captured in patients' houses, although a careful search was made for these organisms by means of direct microscopical, centrifugalization, animal inoculation, and cultural methods of examination. Emulsions prepared from infected and also uninfected sandflies have been examined by dark ground illumination for the presence of spirochetes by Poole and Sachs (1934), but without success In view of these negative findings, it is now agreed that sandfly fever is a virus disease and that the cases studied by those observers who found leptospira were in all probability some variety of Weil's disease

EPIDEMIOLOGY

Geographical Distribution

the climatic conditions are dry and arid,
r sandflies
rontier at Peshawar and Chitral, in the Central Provinces, and Northern Punjab At Chitral it was originally described as "Chitral fever" by McCarrison in 1906 A map showing the distribution of sandfly fever in different parts of India appears in the report of Megaw and Gupta (1927). (See also Young *et al*, 1926, Fawcus, 1930, 1933, Poole and Sachs, 1934, Anderson, 1939, 1941)

The U.S.S.R At Tashkent in Turkestan, cases have been reported by Raevsky (1929) and Petrov (1929 *a*), at Tiflis in Transcaucasia by Gridnew (1928), and in the Crimea by Petrov (1929 *b*) and Kremer (1930)

to suggest that *P. perniciosus* Newst., *P. minutus* Rondani, *P. sargenti* Parrot, and *P. caucasicus* Marzinowsky may be carriers of infection (see Viskovsky and Petrov, 1927, Newstead, 1911, Young, Richmond, and Brendish, 1926, Janbon, Harant, and [illegible]

1947).

CLINICAL FEATURES

The bite of a single insect is sufficient to infect a susceptible person (Birt, 1910 *a*). The site of trauma later becomes painful and tender and may show vesicle formation at its center, so that the lesion may superficially resemble that of chicken-pox.

With regard to the length of the *incubation period*, Castellani and Chalmers (1910) state that it may vary from a few hours to 5 days, but rarely 6 days, whereas Jewell and Kauntze (1932), who have studied cases in Kenya, maintain that it extends from 6 to 7 days but may vary from 3 to 9 days. Shortt, Poole, and Stephens (1934) found during the course of their experimental work that human volunteers who were bitten by infected sandflies developed the disease in 3 to 10 days' time. Volunteers who were experimentally inoculated with infected blood complained of symptoms after 3 to 4 days.

The *onset* is usually sudden and there may be prodromal symptoms. The disease starts with an initial chill or rigor which is accompanied by retro-ocular headache together with aches and pains in the muscles and joints of the back and legs.

Flushing of the face occurs and *the conjunctivae* become so markedly injected that they resemble the eyes of a bloodhound or mastiff, and hence the origin of the name *die Hundskrankheit*, or "dog disease," applied to it by the German writers (Taussig, 1905).

The *skin* is hot, dry, and irritable as the result of repeated scratching, and small vesicles and spots may appear on the fauces, tongue, and palate of the mouth.

Eye lesions such as conjunctivitis, neuroretinitis, and papilledema have been described by Jayle and Mastier (1935), Rameev (1936), and Shee (1942).

"Harara" is a skin condition produced by repeated bites and pruritus following the attacks of sandflies. It is commonly seen among newcomers to Palestine, and takes the form of an urticarial skin eruption confined to the face, arms, and legs. Small vesicles and papules about 7 mm in size develop in due course, and these become filled with clear or blood-stained fluid. At first the fluid is bacteriologically sterile, but later becomes invaded by organisms (see Doerr and Russ, 1909, Dostrowsky, 1925, and Szentkirályi and Lorincz, 1933).

Theodor (1935) reinvestigated the etiology of *harara*, and made the interesting observation that the skin reaction to the bite of the sandfly is a sensitization phenomenon which is acquired relatively quickly, and is later followed by desensitization. It has been claimed that the production of a wheal may localize virus, and protect against further invasion (Fleming, Bignall, and Blades, 1947).

The *temperature* is characteristic of the disease and usually rises to about 104° F. during the first 24 hours of the illness and thereafter declines, to reach normal 3 days later (see Fig. 37). Occasionally a terminal rise of temperature occurs (see McArthur *et al.*, 1930).

Pulse. A slow rate is frequently observed in sandfly fever, and Shortt *et al.* (1934) have stressed the value of bradycardia as a point of importance in the differential diagnosis of sandfly fever from other causes of pyrexia. The slow pulse may be present during the illness and persist throughout convalescence. Le Gac (1937) also mentions the value of bradycardia as a sign of diagnostic significance in the differentiation of pappataci fever from dengue, and adds that a slow pulse rate is due to cerebral hypertension.

sandflies in captivity to feed every second day, but Young, Richmond, and Brendish (1926) maintain that under ordinary conditions the female only feeds once, and is fertilized during the first 36 hours of adult life. After a meal it remains in houses for 60 to 78 hours, returns to its breeding ground, lays its eggs within 108 hours, and may repeat the process of feeding and oviposition a second time. Presumably, therefore, infection of the human being would occur during the second meal.

For fuller information regarding the life history and bionomics of *P. papatasii* the reader is referred to the work of Whittingham and Rook (1923 *a, b*) and Newstead (1911). Other data dealing with the conditions necessary for the breeding of different species of sandfly, their survival in nature, and captivity are contained in the researches of Marett (1915), Smith, Mukerjee, and Lal (1936), Raja (1936), and Smith, Mukerjee, and Halder (1936).

Experimental Work on *Phlebotomus papatasii*

Doerr and his coworkers were the first to prove that infected sandflies could be transported from an endemic area of the disease to a country in which it did not occur, and the infection reproduced in the latter, by permitting the insects to bite human volunteers This observation has received the independent confirmation of subsequent workers (see Birt, 1910 *a*, Whittingham, 1924; Shortt, Poole, and Stephens, 1934; and others), and the rôle of *P. papatasii* is established beyond all doubt Doerr, Franz and Taussig (1909 *a, b*) and Birt (1910 *a*) stated that insects which had fed less than 7 days before were noninfective to volunteers. A similar conclusion was arrived at by Shortt, Poole, and Stephens (1934), who found the period to vary from 6 to 8 days Reports indicate that the virus may survive for a time in the insect vector during its metamorphosis According to Doerr *et al.* (1909 *a*) it can be transmitted by an infected female sandfly through its eggs to the second generation. Whittingham (1924) suggests that this method is unlikely, and he has shown that the virus can be transmitted from one generation of sandflies to another in their breeding grounds by larvae which may have ingested the dejecta or dead bodies of their parents. The flies which acquired infection in this manner became infective to man, but only after they had received their first meal of blood Whittingham's findings have been contradicted by Young, Richmond, and Brendish (1926), who concluded from their own experiments that under normal conditions the female of *P papatasii* did not die in its breeding ground after oviposition Neither did the young larvae exhibit any preference for feeding upon the dead bodies of adult flies when other pabulum was accessible. Young and his colleagues maintain that an infection of the insect in its breeding ground must be postulated They dismiss the idea that this occurs by larvae eating the dead bodies of infected flies for the reasons mentioned above, and suggest that as about 4 per cent of sandflies are infested by acarian parasites (*Raphignathus yongi* Hirst, and *Trombidium hindustanicum* Hirst) These may act as intermediate carriers

Important work confirming the original contention of Doerr has been published by Mochkovski *et al* (1937). They showed that transovular transmission occurs, and that infection is transmitted to man by the bite of females of the second generation hatched from eggs laid by the parent 6–8 days after the infecting feed. Infection was produced by the bites of newly hatched sandflies, showing that no activation by a blood meal is needed

The position is still in doubt, however, for Sabin, Philip, and Paul (1944) infected larvae with virus, but did not find the adults to be infective, flies hatched from the ova of infected females were likewise noninfective

Other Possible Insect Vectors

Apart from *P papatasii*, very little is known about the species of sandfly concerned in the transmission of sandfly fever The presence of human cases, coupled with the existence of insects in proximity to patients, has prompted many observers

DISTRIBUTION OF THE VIRUS

The virus is constantly to be found in the blood in the early stages of the illness. Blood serum remains infective for some weeks if kept in the ice chest.

There is some difference of opinion regarding the duration of infectivity. Sabin, Philip, and Paul (1944) found virus in the blood 24 hours before and after the onset of fever, but not 40 hours after.

On the other hand, Shortt *et al.* (1940) found virus in the blood for a much longer time, up to 7 and sometimes up to 40 days or more

PROPERTIES OF THE VIRUS

Filtrability

Doerr (1908) proved that the causal agent of sandfly or pappataci fever was small enough to pass through the pores of a Reichel earthenware filter. Later, Birt (1910 *a, b*) filtered infective blood through a Chamberland F bougie, diluted it 1 9 in saline, and reproduced the disease in a volunteer with an inoculation equal to 0 7 c c. of undiluted blood.

Tedeschi and Napolitani (1911 *a, b*) and Graham (1915) used the Berkefeld filter, and Kligler and Ashner (1928), who employed the Berkefeld N candle, found that as little as 0.1 c c. of serum was enough to infect a susceptible individual Shortt, Poole, and Stephens (1934) reproduced sandfly fever in human volunteers by inoculating them with Chamberland L_3 and L_5 filtrates of infected blood They also produced a febrile reaction in *M. rhesus* monkeys with human blood which had been passed through the Chamberland L_{13} bougie

Size

Shortt, Pandit, and Rao (1938) used virus cultivated on the chorio-allantoic membrane and estimated the size at 160 mμ by filtration Sabin, Philip, and Paul (1944), however, suggested the virus was of about the same size as that of yellow fever.

Resistance to Physical and Chemical Reagents—Preservation

The virus is killed by heating to 55° C. for 10 minutes (Lépine, 1927), it has been stored for 7 days at 75 to 80° F. (Birt, 1910 *a*), and resists 2 per cent. sodium citrate and 50 per cent. glycerol for 14 days (Shortt, Poole, and Stephens, 1934) The virus withstands drying and can be preserved, by desiccating sera removed from patients on the first or second day of the illness, over sulfuric acid *in vacuo* (Shortt, Poole, and Stephens, 1936) It can be preserved for at least 6 months by

Cultivation in the Developing Egg

Shortt, Rao, and Swaminath (1936) have employed the original method devised by Woodruff and Goodpasture (1931, see Ch. XIII) for the cultivation of sandfly fever virus on the chorio-allantoic membrane of the chick embryo (see Rao, Pandit, and Shortt, 1936). Fourteen- to fifteen-day-old embryos were inoculated either

else with

the pres-

ions there

was a distinct thickening of the membrane, at the center of which was a dense opaque patch measuring about 10 mm in diameter. Examination of such material showed massive growth of inclusion material in the cells of the mesoderm; the

The disease in children has been studied by Peschle (1936), who states that the condition manifests itself as a mild febrile disturbance which may be accompanied by intestinal symptoms.

Nervous system. Trabaud (1930, 1931) attributes the aches and pains experienced in sandfly fever to the action of the virus upon the posterior part of the cord.

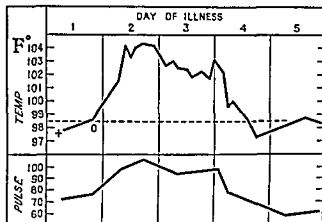

FIG. 37. Temperature chart in a case of sandfly fever.
(After Doerr, Franz, and Taussig, 1909)

Le Gac and Albrand (1937) examined the fluid in 14 cases of the disease and found that there was an increase in the pressure, albumin, and cell content, varying from 10 to 20 cells per c.mm The color of the fluid and its sugar content were normal and no cultivable bacteria were found (see also Le Gac, Samara, and Servant, 1939). It has been suggested that there is an increased blood-tissue permeability in sandfly fever (Gontaeva, 1943) Nervous symptoms may be sufficiently pronounced to simulate lymphocytic choriomeningitis (Pearson, 1941, Fleming, Bignal, and Blades, 1947)

Blood A leukopenia is the most characteristic change, and Whittingham (1922) has recorded that on the 4th day of the disease the total white cell count may fall to 3,500 per c mm Sabin, Philip, and Paul (1944) made a detailed study of the experimental disease. On the 1st day of fever, the total count was within normal limits, but there was a relative and absolute decrease in lymphocytes, and a relative and sometimes absolute increase in neutrophils due to an increase in immature cells. During the 2nd and 3rd days of fever, the number of lymphocytes began to return to normal At the same time the number of segmented neutrophils began to drop, and the immature cells increased to a point where they outnumbered the segmented cells. In certain patients, monocytes increased to constitute 16–40 per cent. of all leukocytes in the febrile and early postfebrile periods Leukopenia may be expected in 90 per cent of cases, chiefly at the end of the febrile period, and in the first 2 days of the postfebrile period

The urine is diminished in quantity during the febrile stage, but is otherwise normal in its constituents

The progress of convalescence varies in different cases. It may either be rapid and uninterrupted or else complications such as amnesia, mental depression, lethargy, bronchitis, or phlebitis may supervene Ocular changes have been described by Rameev (1936) Transverse furrows on the thumb and finger nails have been described (Mochkovski, 1937).

Mild attacks. Anderson (1941) recognizes a mild type of disease, seen on the northwest frontier of India.

IMMUNITY REACTIONS

Second and even third attacks of sandfly fever are not uncommon, even within one season (e g , Lambert, 1918, Janbon, Harant, and Chaptal, 1942) However, there seems little doubt that an attack does confer a certain degree of resistance, perhaps not evident for several months (McCarrison, 1915, Lambert, 1918, Lépine, 1927, Shortt, Poole, and Stephens, 1935, 1936, Livshitz, 1937, Sabin, Philip, and Paul, 1944, Cullinan, 1946)

The inhabitants of endemic areas almost certainly develop active immunity, presumably as a result of repeated infection, and, for example, it has frequently been found that newly-arrived European soldiers are more readily attacked than the local inhabitants.

Some attempts have been made at immunization by inoculation of live virus in man, and it is probable that some protection follows (Livschitz, 1937, Sabin, Philip, and Paul, 1944). The latter workers also used virus irradiated by UVL.

After inoculation of live virus, virus may be recovered from the blood, and neutralizing antibodies develop later (Shortt *et al*, 1940)

As first shown by Doerr *et al* (1909 *a*), virus neutralizing antibodies develop in convalescence in man Antibodies can be demonstrated by inoculation of virus-serum mixtures in monkeys, eggs, or even man

Virus neutralizing antibodies develop also in the sera of convalescent monkeys (Shortt *et al*, 1940)

PREVENTION OF SANDFLY FEVER

Advantage has been taken of the fact that the insects fly comparatively near the ground, and consequently individuals who sleep in the upper part of a house may escape being bitten In the case of military camps, removal to higher ground has had a similar effect (see Whittingham and Rook, 1923 *a*). Anderson (1939), however, reports that sandflies can fly up to 70 feet above ground, and that there is no evidence that persons in upper stories are protected, sandflies cannot fly against a wind of more than about 2 m p h The insects are attracted by light, and traps have been used for this purpose. Extrinsic factors such as atmospheric temperature and relative humidity have been found to affect the development of infectivity for man.

The following control measures have been recommended for military camps (*Bull U S Army med Dept*, 1945). The site should be on open, raised, dry,

shirts and full-length trousers must be worn Insect repellent on exposed parts of the body protects for 4–6 hours, dimethyl phthalate and pyrethrum are effective (Sabin, Philip, and Paul, 1944) For further information on the use of DDT, see Hertig and Fairchild (1948) and Semple (1948)

cytoplasm of many cells appeared to have been wholly replaced by red-staining inclusion material but no characteristic inclusion bodies could be detected

These observations have been confirmed (Shortt, Pandit, and Rao, 1938, Shortt *et al.*, 1940, Demina, 1941 *a*, Khodukin, Soshnikova, and Kevorkova, 1943); the virus has been carried through numerous passages. The microscopical appearances are those of a proliferative necrosis, desquamation of the ectoderm, infiltration of the mesoderm, and proliferation of the entoderm (Demina and Levitanskaja, 1940). These authors reproduced the disease in man with a suspension of membrane.

Tissue Cultures

The virus has been cultivated in tissue cultures containing finely minced chick embryo, Tyrode, and human serum (Shortt, Pandit, and Rao, 1938, Shortt *et al.*, 1940). The culture virus was not pathogenic to mice or monkey. Demina (1941 *a*) also cultivated the virus.

HUMAN TRANSMISSION

In addition to those mentioned elsewhere in the text, a number of workers have transmitted the infection by injections of blood or serum or by the bites of infected sandflies (Anderson, 1941, Gontaeva, 1943, Sabin, Philip, and Paul, 1944, Fleming, Bagnall, and Blades, 1947). Sabin, Philip, and Paul passed the infection in series 7 times. The most effective route of inoculation was the intracutaneous or intravenous, the subcutaneous and intramuscular routes were less sensitive.

In Russia apparently sandfly fever is regularly transmitted in the treatment of schizophrenia (see Livshitz, 1937; Khodukin, Soshnikova, and Kevorkova, 1943)

ANIMAL INOCULATION EXPERIMENTS

Monkeys are mildly susceptible Tedeschi and Napolitani (1911 *b*) inoculated *Macacus cynomolgus* with 0 5 c c of a Berkefeld filtrate of human serum, and succeeded in reproducing a transient febrile illness After an incubation period of 7 days the temperature rose from 37 5° C to 38 2° C, and 3 days later it reached 39.3° C

More recently the work of Shortt, Poole, and Stephens (1934) has shown that the virus of sandfly fever is also feebly pathogenic towards *M rhesus* Thus, 5 out of 11 animals which were inoculated with 10 c c. of infected human blood developed a slight rise of temperature, attaining 103° F 3 to 4 days after inoculation The illness lasted from 1 to 5 days, and during this period the blood of one monkey proved infective to another animal of the same species It was also possible to reproduce a mild attack of sandfly fever in 2 human volunteers by injecting them with 5 c c. of infected monkey blood Later, Shortt *et al* (1940) recovered virus from the blood of monkeys, up to a maximum of 19 days after onset

Dogs, rabbits, and *guinea-pigs* have been inoculated with negative results (Tedeschi and Napolitani, 1911 *a*, Poole and Sachs, 1934) Apparently, Russian workers claim to have infected rabbits by "suboccipital" injection (see Khodukin and Shterngold, 1943) These workers could not infect mice intracerebrally.

Sabin, Philip, and Paul (1944) could not infect monkeys, mice, hamsters, rabbits, guinea-pigs, and cotton rats Birt (1910 *a*) also found that the virus was not pathogenic to laboratory animals

LABORATORY DIAGNOSIS

The virus survives in blood and serum for some considerable time, and samples may be mailed to the laboratory, where monkeys should be inoculated Of particular value is the susceptibility of the chorio-allantois (see Anderson, 1941)

were no evident changes (Koprowski and Hughes, 1946, Laemmert and Hughes, 1947).

On intracerebral injection of a marmoset (*Callithrix jacchus*), virus circulated in the blood for 7 days, and the animal died, virus being recovered from the brain. Another animal of the same species, on intraperitoneal injection, showed virus in the blood for 5 days. Another species of marmoset (*Callithrix penicillata*) showed virus in the blood for 5–7 days after intracerebral or subcutaneous injection (Koprowski and Hughes, 1946).

It is evident that marmosets circulate virus in the blood for longer than do the other primates tested. This species is abundant in the forest at Pirataquissé, the locality from which Ilhéos virus was obtained.

Rodents

After intracerebral or subcutaneous inoculation, the following rodents showed virus in the blood stream for 2–5 days: *Oryzomys ratticeps*, *Proechimys dimidiatus*, white rats, guinea-pigs, and rabbits (Koprowski and Hughes, 1946). None of these animals showed any symptoms of encephalitis.

Marsupials

Four species of marsupial were tested by Koprowski and Hughes (1946), and showed considerable variation in response: *Metachirops opossum* and *Didelphis marsupialis* were not readily infected, *Caluromys philander* showed virus in the blood for 3 days after intracerebral injection, and after subcutaneous inoculation, *Metachirus nudicaudatus* showed virus in the blood for 8 days after intracerebral, and 9 days after subcutaneous injection. One of these animals died, and virus was found in the brain.

Other Animals

The domestic hen, the pigeon, and a local canary were tested by Koprowski and Hughes (1946). None developed encephalitis, and virus had disappeared from the blood in 3 days. Virus persisted in the brains of some canaries after intracerebral injection for at least 30 days. Virus was demonstrated in the serum of the leaf-nosed bat (*Carollia perspicillata*) for 6 days after intracerebral injection, following subcutaneous injection, vampire bats (*Desmodus rotundus*) showed virus in the blood for a maximal period of 3 days (Koprowski and Hughes, 1946).

EXPERIMENTAL TRANSMISSION BY MOSQUITOES

Groups of mosquitoes were infected by feeding on baby mice showing viremia. *Aedes aegypti* infected baby mice fairly readily. *Aedes serratus* and *Psorophora ferox* could also transmit the infection (Laemmert and Hughes, 1947).

On the basis of the results of animal experiments described above, Koprowski and Hughes (1946) suggested that the Ilhéos virus is maintained in nature by alternate passages between marmosets and mosquito vectors, with perhaps occasional passages to marsupials or rodents.

OTHER PROPERTIES OF THE VIRUS

Physical Properties

The virus is filtrable through Seitz EK and Berkefeld filters (Koprowski and Hughes, 1946).

Reaction to Physical and Chemical Agents

Virus can be preserved by freezing and dehydrating suspensions in human serum (Koprowski and Hughes, 1946).

The thermal death point lies between 60° and 65° C (Koprowski and Hughes, 1946).

CHAPTER XLV

THE VIRUS OF ILHÉOS ENCEPHALITIS

ISOLATION

The virus of Ilhéos encephalitis was isolated in the course of yellow fever studies from mosquitoes captured in the vicinity of Ilhéos in the State of Bahîa (Brazil) by Laemmert and Hughes (1947). Mosquitoes of the *Aedes-Psorophora* group were collected at Pirataquissé, located in forested country. An emulsion was injected at daily intervals for an 8-day period into a rhesus monkey. Serum was obtained from this animal at 3-day intervals, and injected into 21–27-day-old Swiss mice. Some mice showed signs of illness, and their brains were passed. The Ilhéos virus was isolated and readily maintained through 50 mouse passages.

There appears to be no doubt that the virus was isolated from the captured mosquitoes. Serum taken from the rhesus monkey before inoculation contained no antibodies neutralizing the virus, but serum removed about 10 weeks later contained such antibodies.

Another rhesus animal inoculated a month later with emulsions of *Aedes-Psorophora* mosquitoes from Pirataquissé developed antibodies after 21 days.

INFECTION IN MAN

The virus can set up an antibody response in man, but there is no evidence that it causes an overt infection (Laemmert and Hughes, 1947).

INFECTION IN ANIMALS

Mice

Virus was readily maintained by serial brain-to-brain passage in albino Swiss mice derived from the original Rockefeller stock (Koprowski and Hughes, 1946). The average survival time was found to be 6 days in early passages, and 4 days in the 40th passage, the incubation period decreased from 5–3 days. After intraperitoneal injection, virus invades the blood, but disappears completely by the 3rd day, there is, on the contrary, a rapid increase in virus content of the brain tissue, reaching a maximum at about the 3rd day, after which it remains at a uniformly high level. The virus can be found also in spinal cord, lungs, kidneys, adrenals, spleen, liver, and intestines, when these are tested 120 hours after intraperitoneal injection (Koprowski and Hughes, 1946). There is a marked loss in susceptibility to extraneural (intraperitoneal) inoculation in mice of 28 days or older, as compared to younger animals (8–21 days) (Koprowski and Hughes, 1946). Mice of 8 days old are almost equally susceptible to subcutaneous, intracutaneous, intraperitoneal, intranasal, or intracerebral injection (Koprowski and Hughes, 1946). Laemmert and Hughes (1947) found baby mice (3 day) particularly susceptible to subcutaneous injection. A proportion of adult mice who devour infected baby mice becomes infected. The infection is not spread by cage contact, as distinct from cannibalism (Koprowski and Hughes, 1946). The brains of infected mice, regardless of the route of inoculation, show encephalitis characterized by hyperemia, small foci of hemorrhage, and mononuclear infiltration (Koprowski and Hughes, 1946).

Monkeys

On intracerebral inoculation in *Macaca mulatta*, virus circulates in the blood from 3–6 days after inoculation, one monkey was noted to become paralyzed on the 12th day after injection, and virus was recovered from its brain, although there

CHAPTER XLVI

COLOMBIAN VIRUSES OF ROCA-GARCIÁ

Roca-García (1944) isolated 3 viruses in the course of studies on the epidemiology of jungle yellow fever in Eastern Colombia. Two viruses were isolated from lots of the *Anopheles* mosquito (*Kerteszia boliviensis*), and have been named "*Anopheles A*" and "*Anopheles B*" viruses The 3rd was isolated from *Wyeomyia melanocephala*, and was accordingly named "Wyeomyia" virus (it has also been called "*Sabethine I*"). There is no evidence that these agents are pathogenic for man

Anopheles A Virus

The virus passes through Seitz EK pads, and all grades of Berkefeld filter The virus can be preserved by drying from the frozen state, but not satisfactorily in glycerol. Virulence is lost in 30 minutes at 55° C.

On intracerebral inoculation, mice develop paralysis and die by 5 days On intranasal inoculation, virus invades and multiplies in the brain, it is also found in the lungs Adult mice are relatively insusceptible to peritoneal inoculation, but develop resistance even to intracerebral challenge. Adult mice are unaffected by subcutaneous injection, although developing a slight degree of resistance Baby mice are very susceptible to virus inoculated by this route. Virus was recovered from the blood of adult mice irregularly on the 2nd and 3rd days after injection, especially by the intracerebral route Virus is found in the brain, cord, and adrenals

Rhesus monkeys and guinea-pigs do not show symptoms, but may develop viremia

The following animals did not show signs of illness, but developed antibody: *Didelphis marsupialis*, *Metachirus nudicaudatus*, *Metachirops opossum*, *Dasyprocta*, *Dasypus*, and *Cabassous* Pigeons did not develop viremia, and antibodies did not appear

The virus has been carried through 10 serial passages in the fertile egg, inoculated directly into the embryo. It has also been cultivated in minced mouse embryo in Tyrode with 10 per cent human serum

Anopheles B Virus

The virus passes through Seitz EK pads and all grades of Berkefeld filter

Virulence is not retained for long when virus is dried from the frozen state, but may be preserved in glycerol Virulence is lost in half an hour at 55° C.

The symptoms in mice are different from those shown by animals infected by the other viruses The incubation period is about 5 days, and mice die a few hours after the onset of illness, without paralysis Adult mice can be infected nasally and cerebrally. Baby mice do not develop symptoms after subcutaneous inoculation. Viremia does not occur in mice infected with this virus

Guinea-pigs develop no illness and no viremia.

The virus has been cultivated in minced mouse embryo in Tyrode with 10 per cent human serum

Wyeomyia Virus

The virus passes through Seitz EK pads and all grades of Berkefeld filter.

The virus can be preserved by drying from the frozen state, but not readily in glycerol

Adult mice inoculated cerebrally or nasally, and baby mice inoculated subcutaneously, show the same type of reaction as to *Anopheles A* (above), except that the incubation is a little longer The virus is more widely distributed in the bodies

Virus loses infectivity in saline more rapidly than in 10 per cent. serum saline, in both media, activity is lost at the end of 20 days (Koprowski and Hughes, 1946).

Some infectivity is retained in infected brains in 50 per cent. neutral glycerol (Koprowski and Hughes, 1946).

Cultivation

The virus was readily cultivated in *tissue cultures* prepared from minced chick embryo (without CNS) in serum Tyrode (Koprowski and Hughes, 1946)

The virus was also cultivated on the chorio-allantois, and invaded the embryo (Koprowski and Hughes, 1946).

VIRUS NEUTRALIZATION TESTS

Technique

Virus neutralization tests can be performed by inoculating virus-serum mixtures intracerebrally in 22-day-old mice, but the method is not regarded as being sufficiently sensitive (Laemmert and Hughes, 1947). Antibodies are best demonstrated by inoculating virus-serum mixtures subcutaneously in 3-day-old mice, and observing for 15 days. Death usually occurs between the 5th and 10th days (Laemmert and Hughes, 1947).

Occurrence of Virus Neutralizing Antibodies

Virus neutralizing antibodies have been found in the sera of rhesus monkeys after cerebral or peritoneal inoculation (Koprowski and Hughes, 1946, Laemmert and Hughes, 1947), antibodies also develop in *Cebus versuta*, and marmosets (Koprowski and Hughes, 1946) Antibodies have been detected in rats, guinea-pigs, rabbits, various rodents, and marsupials (Koprowski and Hughes, 1946).

Antibodies were detected in the blood of a laboratory worker during the course of experiments He had had no illness (Laemmert and Hughes, 1947). Antibodies were also found in the sera of 3 persons resident in the Ilhéos area, and less strongly developed in the sera of 2 other persons (Laemmert and Hughes, 1947).

RELATIONSHIP TO OTHER VIRUSES

Antisera to the following viruses failed to neutralize Ilhéos virus significantly, when mixtures were tested subcutaneously in baby mice yellow fever, eastern, western, and Venezuelan equine encephalomyelitis, St Louis, Japanese B, and West Nile encephalitis, LCM, louping ill, Russian spring-summer encephalitis (Laemmert and Hughes, 1947).

In other tests, dilutions of various viruses were mixed with Ilhéos monkey antiserum Ilhéos serum did not neutralize *Anopheles A* or *Wyeomyia* viruses of Roca-García, Japanese B, or West Nile viruses (Laemmert and Hughes, 1947).

Ilhéos virus differs from *Anopheles B* virus, which is not infective for baby mice subcutaneously, Ilhéos infection of mice also differs clinically and histologically from that caused by Theiler's virus (Laemmert and Hughes, 1947)

Although precise tests have not been carried out, the properties of Ilhéos and Semliki Forest viruses appear distinct.

CHAPTER XLVII

WEST NILE VIRUS

ISOLATION

This virus was isolated by Smithburn *et al.* (1940) from an African woman in December, 1937, in the West Nile district, Northern Province of Uganda. She had a temperature of 100.6° F. A sample of her blood was taken, and a virus was established in mice by cerebral inoculation.

DISTRIBUTION OF INFECTION IN MAN

Smithburn and Jacobs (1942) carried out an epidemiological survey, and examined the sera of 1,428 residents in 63 localities in the Anglo-Egyptian Sudan, Kenya, Uganda, the Belgian Congo, and Spanish Guinea. They found that the virus apparently had been active in the Sudan, Uganda, Kenya, and the Congo In the region where the West Nile virus was isolated in 1937, a survey carried out 2 years later showed that the sera of 16 per cent. of persons tested contained neutralizing antibody.

INFECTION IN ANIMALS

Mice

Smithburn *et al* (1940) found that the virus is infective by either the cerebral, nasal, or peritoneal routes The incubation period, by the cerebral route, may be only 2–3 days, when mice become hyperactive, later they become sluggish and weak, and paralysis of the hind legs may occur. Death takes place 12–72 hours after the first signs of illness

After cerebral or peritoneal inoculation, the virus enters the circulation and persists therein. Virus inoculated peritoneally reaches a high titer in the brain by the 3rd day.

Lesions do not occur regularly in the visceral organs, but are generalized in the brain There are perivascular lymphocyte infiltrations, and the cerebral nuclei and cortical pyramidal cells show the principal changes. Many nuclei appear vesicular. Some pyknotic degeneration of nerve cells is also present, especially in Ammon's horn The most outstanding change affects the pyramidal cells of the cortex, the cells of the cerebral nuclei, and the Purkinje cells of the cerebellum There is retraction of the processes, and slight shrinkage of the cells, which stain acidophil in cytoplasm and nucleus No inclusions are found

Working with mouse-passaged virus, it was shown that susceptibility to fatal infection by the cerebral route is unaffected by age, susceptibility to extraneural inoculation, however, decreases with increasing age of the animal, animals 21 days old being found refractory (Lennette and Koprowski, 1944 *a*, *b*)

Monkeys

[illegible]

be viremia. Antibodies develop in convalescence. After intravenous inoculation, there is fever without clinical signs of encephalitis, the animals develop antibodies and resistance (Smithburn *et al.*, 1940). The histological changes are similar to those in mice (see above).

On cerebral inoculation in *Cercocopithecus aethiops centralis*, the virus enters the circulation and induces the formation of antibodies.

of paralyzed mice than is the *Anopheles A*, being found in liver, spleen, lungs, and heart, as well as adrenals, cord, and brain.

No signs of infection follow inoculation of rhesus monkeys, *Didelphis marsupialis*, rabbits, or guinea-pigs

Cross Immunity and Cross Neutralization Tests

Intraperitoneal inoculation of all 3 strains rendered mice resistant to a cerebral challenge of the homologous agent, but not resistant to the heterologous viruses. The 3 viruses appear immunologically distinct. Mice immunized against *Anopheles A* showed a certain measure of protection against Theiler's virus (GDVII strain), but otherwise there was no indication that any of the mosquito viruses produced immunity to this agent.

Yellow fever immune sera did not neutralize the 3 viruses.

Immune sera to the following viruses did not neutralize *Anopheles A* virus eastern and western equine encephalomyelitis, St Louis and Japanese encephalitis, West Nile virus, and distemper virus.

REFERENCE

Roca-García, M (1944), *J infect Dis*, 75, 160

IMMUNITY REACTIONS

Antigen-Antibody Reactions

Most work has been carried out with the virus neutralization test. Virus neutralizing antibodies can be detected by the intracerebral inoculation of virus-serum mixtures in mice. Lennette and Koprowski (1944 *b*) have introduced a mouse protection test using the susceptible young mouse (up to 14 days of age). Virus-serum mixtures are injected subcutaneously in 3-day-old mice, or intraperitoneally in 8- or 14-day-old animals. The neutralizing power of antisera estimated by the extraneural routes is 38,000–78,000 times that shown by the cerebral routes

An antigen can be prepared from mouse- or hamster-infected brain that fixes complement with specific antisera, the infectivity of such antigens is destroyed by exposure to ultraviolet light (Havens *et al.*, 1943). Casals (1944) has also prepared a complement fixing antigen from infected brain (see also 1947).

Immunity in Man

The serum of the original case was found to neutralize the virus, when tested 3 months later; antibodies developed in the sera of 2 persons studying the virus, although they had no illness (Smithburn *et al*, 1940).

It is highly likely that subclinical, and probably clinical, infections occur over widely separated areas in Africa and give rise to serum antibodies (Smithburn and Jacobs, 1942).

Immunity in Animals

Active immunity.

Monkeys develop resistance to infection following inoculation with living virus (Smithburn *et al.*, 1940) Hamsters that survive infection become resistant to reinoculation (Havens *et al*, 1943). Mice can be actively immunized (Smithburn, 1942; Casals, 1944).

Serum antibodies in convalescence.

Experimental animals, recovered from infection with the virus, develop virus neutralizing and complement fixing antibodies. High titer sera for use in serological tests can be prepared in monkeys (Smithburn, 1942), guinea-pigs, or mice (Casals, 1944), rabbits (Lennette and Koprowski, 1944 *b*), or hamsters (Havens *et al*, 1943).

Nonspecific virus neutralization.

Koprowski (1946) found that the sera of certain species of marsupial and rodent captured in Brazil, notably *Didelphis marsupialis* and *Oryzomys*, in addition to neutralizing yellow fever virus, inactivated Japanese B, St. Louis, and West Nile viruses These latter agents are not known to occur in Brazil. This antiviral activity was believed to be due to the presence of some nonspecific substance unrelated to infection with yellow fever The inactivation could be demonstrated by both the intracerebral and intraperitoneal techniques The virus-inactivating substance was not destroyed at 56° C The quantity of the substance present in the blood fluctuated, but might be enough to inactivate a very high concentration of yellow fever virus.

RELATIONSHIP BETWEEN WEST NILE, ST. LOUIS AND JAPANESE B VIRUSES

This question has been investigated in cross resistance and cross neutralization tests, the CF technique has also been used.

1 Mice rendered resistant to St Louis or Japanese viruses are not resistant to West Nile virus (Smithburn, 1942) Mice rendered resistant to West Nile virus succumb to infection with St Louis or Japanese B viruses (Smithburn, 1942).

Infection in other Animals

No signs of illness develop in inoculated rabbits or guinea-pigs, but antibodies are stimulated (Smithburn *et al.*, 1940).

Hamsters

These animals are susceptible to virus inoculated cerebrally or peripherally (Havens *et al*, 1943; Watson and Smadel, 1943). The incubation period is 7–10 days. Some hours before death, the animals become spastic, exhibit coarse tremors and convulsions. Virus appears in the blood within 24–48 hours of intraperitoneal inoculation, and is demonstrable in the blood or spleen before the brain

PROPERTIES OF THE VIRUS

Filtrability

The virus passes through all grades of Berkefeld filter and Seitz EK pad (Smithburn *et al.*, 1940). The size of the virus has been calculated by filtration experiments at 21–31 mμ (Smithburn *et al*, 1940).

Reaction to Physical and Chemical Agents

The virus is readily preserved by drying from the frozen state (Smithburn *et al.*, 1940). It is destroyed by heating at 55° C. for half an hour It is slightly more resistant to heat when suspended in serum (Smithburn *et al.*, 1940).

Cultivation in Eggs

Virus multiplies readily in embryonated eggs inoculated by the chorio-allantoic, yolk sac, or allantoic routes (Watson, 1943). Embryos become sluggish and die in 2–5 days. Virus becomes distributed throughout the egg, although the allantoic fluid only contains small quantities Titrations can be performed by inoculation in eggs

Cultivation in Tissue Culture

Koprowski and Lennette (1946) studied the effect of prolonged cultivation *in vitro*. The virus was found to grow equally well in media containing mouse embryo brain, whole mouse embryo, whole chick embryo, or chick embryo without the CNS, the latter was adopted for routine use. Virus persisted in cultures for a very long time—at least 32 days. The lethal effects for mice and hamsters by the cerebral route were not altered during 79 transfers, although there was some prolongation of the survival time The continued propagation of the virus resulted in a marked attenuation of its ability to kill mice on extraneural inoculation Inoculated by the peritoneal route, in 21–28-day mice, decreased virulence was shown in the 26th passage, by the 50th passage, culture virus was practically avirulent under these conditions. At the 50th passage, virus killed only an occasional 14-day-old mouse, but was still fully virulent for 8-day and 3-day mice At the 68th passage, there was a decreased virulence for 8-day mice After 79 passages, the virus was found to be avirulent for hamsters by the peritoneal route

Lennette and Koprowski (1946 *b*) found that the 17DD High strain of yellow fever and the West Nile virus suppressed more or less completely the growth of influenza virus (PR8) in tissue culture

Experiments with Mosquitoes

The mosquito *Aedes albopictus* can become infected by feeding on hamsters inoculated with West Nile virus After an incubation period of some days, the mosquitoes can transfer the infection to other hamsters by biting (*Philip and Smadel*, 1943).

CHAPTER XLVIII

BWAMBA FEVER

THE CHARACTER of this disease was described by Smithburn, Mahaffy, and Paul (1941), Bwamba County lies in the Western Province of Uganda, 2300–2500 feet above sea level. It is partly heavily forested, and partly agricultural The natives live as family groups in clusters of huts close to their agricultural holdings During the course of the investigation, native labor was employed on building a motor road, and all persons suffering from fever of undetermined origin were bled. Nine individuals presented symptoms of the disease called Bwamba fever, and the same number of transmissible agents was isolated. All strains appeared identical

Clinical Features

The onset was sudden, with fever and frontal headache. Weakness and backache were present. Fever lasted for 2–5 days (average 101° F.), the headache and backache for 2–3 days longer. Convalescence was rapid and complete The pulse was strikingly slow, averaging 84

Eight of the patients were nonresidents of the area, and had worked in the heavily forested area for 13–83 days before onset.

Possible intermediate animal hosts were numerous, but possible arthropod vectors were not troublesome.

Infection in Mice

Mice are susceptible to intracerebral or intranasal inoculation, but not to intraperitoneal or subcutaneous injections The incubation period varies from 4–6 days according to the dose and route. The first sign of illness is marked hyperactivity, often with exophthalmos Next the animal becomes normally reactive or sluggish, and presents photophobia. Paralysis of the hind quarters is not usual. Virus may be detected in the blood from the 4th–8th day after inoculation.

Microscopically, there is moderate to marked vascular dilatation and congestion of the cerebral blood vessels. Small hemorrhages may occur. Widespread and diffuse degenerative changes occur in the cortical pyramidal cells The nuclei are swollen and foamy or vesicular, with marked derangement of the chromatin pattern Many cells show small round or oval single or multiple intranuclear inclusions. Inflammatory changes are minimal

s inoculated by the
use, however, when
age
with the growth of
Bwamba virus injected by the same route (Vilches and Hirst, 1947).

Infection in Other Animals

The virus causes fever, without other significant signs, on inoculation in rhesus monkeys, and elicits the formation of antibodies. Viremia may occur shortly after inoculation

Rabbits develop no illness following cerebral or corneal inoculation Young guinea-pigs inoculated cerebrally show an irregular febrile response, and develop antibody

Filtrability and Other Properties

The virus passes Seitz EK and Berkefeld filters. Ultrafiltration experiments suggest a size of 113–150 mμ.

Casals (1944) likewise found no evidence of cross resistance in active immunity experiments, and the same conclusions were reached by Lennette and Koprowski (1946 a).

2. However, in neutralization tests with antisera, there is definite cross reaction between the 3 agents, and this complicates the serological diagnosis. Thus St. Louis antisera cross neutralize West Nile virus (Smithburn and Jacobs, 1942, Casals, 1944). Japanese B sera neutralize St. Louis and West Nile viruses (Smithburn and Jacobs, 1942; Casals, 1944). Smithburn (1942) reported that St. Louis and Japanese sera cross neutralize West Nile virus, but the neutralization is less effective than that brought about by the homologous serum. West Nile sera (human, mouse, or monkey) do not neutralize the other 2 viruses (Smithburn, 1942; Casals, 1944) However, Casals (1944) found that high titer West Nile sera prepared in hamsters or guinea-pigs do neutralize Japanese B virus.

The above observations made in adult mice have been repeated by Lennette and Koprowski (1946 a) using the sensitive extraneural test in 3-day-old animals. They found that St. Louis sera neutralized West Nile and Japanese B viruses, Japanese B sera neutralized St Louis and West Nile viruses, West Nile sera neutralized St. Louis but not Japanese B virus

3. Using complement fixing antigens prepared from infected brain tissue, Havens *et al.* (1943) could not demonstrate any cross reaction between the 3 viruses.

Casals (1944), also using complement fixation tests, found that Japanese serum reacted with both St. Louis and West Nile antigens, St. Louis serum reacted with Japanese antigen, and West Nile serum with Japanese antigen

We may conclude that the 3 agents are immunologically distinct, but share small amounts of one or more common antigenic components

RELATIONSHIP TO OTHER VIRUSES

West Nile, Japanese B, and St. Louis viruses are unrelated antigenically to the viruses of Western equine encephalomyelitis (Casals, 1944). West Nile virus is probably related antigenically to the Russian encephalitis virus and louping ill (see Ch. XCVIII) West Nile antisera do not neutralize *Anopheles A* virus (Roca-García, 1944), or the virus of Bwamba fever (Smithburn, Mahaffy, and Paul, 1941). The virus is not neutralized by yellow fever antisera (Smithburn *et al*, 1940) It is distinct from Bunyamwera virus (Smithburn, Haddow, and Mahaffy, 1946).

CHAPTER XLIX

SEMLIKI FOREST VIRUS

THIS VIRUS was isolated from *Aedes abnormalis* mosquitoes caught in a forest in Bundinyama, Bwamba, about 1½ miles from the southern boundary of the Semliki Crown Forest (Smithburn and Haddow, 1944). It was established by intracerebral inoculation in mice.

Pathogenicity for Man

No definite illness has been attributed to this virus, but as antibodies have been detected (see below) it is probable that it is pathogenic. It would presumably be transmitted by *Aedes* mosquitoes, and a reservoir in forest monkeys such as *Cercopithecus nictitans* is probable

Infection in Mice

to 10^{-10} for intracerebral inoculation, to obtain an end point; a final dilution of 10^{-9} usually suffices to detect an end point by abdominal inoculation. The virus is also pathogenic for mice by subcutaneous inoculation, in about the same concentration as by the abdominal route.

Clinically, the first appearance of illness is paralysis in the hind limbs The mice become prostrate, and death not infrequently occurs during convulsions. With large doses of virus, all mice may be dead within 48 hours, with smaller doses, death may be delayed for 5–7 days.

Virus is found in the kidneys in greater titer than in other abdominal or thoracic viscera.

The brain shows hyperemia with small hemorrhages in some animals. There is also some perivascular cuffing with lymphocytes, and sometimes lymphocytic infiltration of the meninges or choroid, or both Microscopic foci of infiltration are found surrounding necrotic nerve cells, especially in the medulla.

Infection in Guinea-pigs and Rabbits

Guinea-pigs and rabbits can be infected intracerebrally with virus of enhanced virulence, but do not succumb from the effects of extraneural inoculation (Smithburn and Haddow, 1944).

Infection in Monkeys

A rhesus monkey inoculated cerebrally with late passage mouse virus developed fever and paralysis, and was dead after 4 days (Smithburn and Haddow, 1944). These workers also investigated the response of wild monkeys. A red-tail monkey (*Cercopithecus nictitans*) was febrile 3–9 days after subcutaneous inoculation, and showed viremia 3 days after inoculation, inoculated cerebrally, this monkey developed encephalitis A blue monkey (*Cercopithecus mitis* Wolf), inoculated cerebrally, developed fever in 48 hours and had viremia. A grivet monkey, inoculated cerebrally, developed encephalitis, but recovered slowly.

Filtrability and Other Properties

The

burn anc

reactions

The virus can be preserved readily by drying from the frozen state It is destroyed by heating at 50° C. for 30 minutes. Serum gives some protection to the virus against the effects of heat and saline solution.

Virus Neutralizing Antibodies

Virus neutralizing antibodies can be detected by inoculating serum-virus mixtures intracerebrally in mice 6–8 weeks old.

Normal human, monkey, rabbit, and guinea-pig sera were not found to neutralize the virus of Bwamba fever.

The virus was not neutralized by antiserum to West Nile virus. It is distinct from Bunyamwera virus

Acute phase sera did ion occurred in convalescence. illness and his convalescent serum neutralized the virus.

CHAPTER L

BUNYAMWERA VIRUS

THIS VIRUS was isolated in Entebbe from a batch of over 4,000 *Aedes* mosquitoes caught in the uninhabited Bunyamwera III district of the Semliki Forest, Bwamba County, Western Uganda, by Smithburn, Haddow, and Mahaffy (1946). The virus was isolated by inoculating a rhesus monkey and was maintained by intracerebral passage in mice.

Pathogenicity for Man

Although not proved, it seems probable that this virus is pathogenic for man. Smithburn, Haddow, and Mahaffy (1946) made the following observations: 53 sera from persons residing on the edge of the Semliki Forest were examined prior to the isolation of the virus, but none contained antibody. The sera of a further 298 residents in Bwamba County were tested about a year after the isolation of the virus, and 10 per cent. contained protective antibodies. The serum of one patient with a suspected virus encephalitis also contained protective antibody.

There may be a reservoir of the virus in monkeys, as the serum of a colobus monkey has been found to contain antibody. Virus could be transmitted to man by *Aedes* mosquitoes.

Infection in Mice

Mice can be infected with the virus (Smithburn, Haddow, and Mahaffy, 1946). The first sign of infection is hyperactivity and hyperreactivity. The animal responds to stimuli by leaping or racing, and runs in circles. Convulsions usually precede death. The animal may survive the hyperactive stage and become paralyzed. Convulsions may occur in this phase also. With 14th passage virus inoculated intracerebrally, the mean survival time in mice receiving 6750 MLD was 3.3 days, with 6 M.L.D. it was 6.5 days. The virus infects mice also by the intraperitoneal, intranasal, and subcutaneous routes. It was transmitted in series only by the intracerebral route. Virus is found in the blood at the time of onset of objective illness. There is more virus in the spleen than other thoracic or abdominal viscera. The lesions produced by the virus are insignificant. The brain shows congestion and hemorrhages in the lateral ventricles. Degeneration of nerve cells is present, especially in Ammon's horn and basal nuclei.

Infection in Monkeys and Rabbits

The virus is not invariably fatal to rhesus monkeys by the subcutaneous route. During a febrile response, virus is found in the blood. Rabbits hyperimmunized with live virus showed no illness, but antibodies developed (Smithburn, Haddow, and Mahaffy, 1946).

Filtrability and Preservation

The virus passes through Seitz EK pads, and all 3 grades of Berkefeld filter. It can be preserved by desiccation from the frozen state, or by storage in glycerol (Smithburn, Haddow, and Mahaffy, 1946).

Virus Neutralizing Antibodies

Pro[illegible] [illegible]tion of mice cerebrally or periton[illegible]. Antibodies were found in the ser[illegible] wild monkey (see above).

loses potency in saline at low temperatures, but retains potency for several weeks in serum in the refrigerator. It survives heating at 60° C. for ½ hour, but not 1 hour. It is inactivated in ½ hour at 62° C.

Cultivation in the Egg

Virus has been successfully propagated through 33 serial passages in the embryo chick (Smithburn, 1946). The series of passages was initiated with a filtrate prepared from an infected mouse brain injected into the region of the developing embryo. Eggs incubated for 7–9 days prior to inoculation were employed. Passage was performed with a filtrate of ground up embryo, injected into the region of the embryo. Virus multiplied readily, and embryos succumbed between the 11th and 24th hours after inoculation. Tests for the presence of virus were made by inoculating mice intracerebrally. The titer of virus in embryonic chick tissue varied between 1 in 3.65 million and 1 in 210 million, and there was no decline on passage. Virus could be detected in the developing embryo from about the 4th hour of incubation onwards The virus content seemed to remain more or less stationary after the death of the embryo The curve of multiplication proceeded, up to 12 hours, by logarithmic progression. Beyond that point, there was a flattening of the curve but a further absolute increase. Macroscopically the embryos showed varying degrees of hyperemia and hemorrhage. Microscopic examination showed dilatation and congestion of vessels and extravasation, especially in the subcutis. Necrosis of cells only occurred to a slight extent and was not marked in any special tissue

Immunity Mechanisms

Antibodies can be demonstrated by inoculation of mice intracerebrally or intra-abdominally with virus-serum mixtures, the abdominal route is preferred (Smithburn, Mahaffy, and Haddow, 1944).

Individuals residing in 4 widely separated areas of Uganda possessed protective antibody Antibodies were also found in 6 primates, especially in *Cercopithecus nictitans* (Smithburn, Mahaffy, and Haddow, 1944).

Antibodies develop in the sera of rabbits, guinea-pigs, and monkeys inoculated with virus (Smithburn and Haddow, 1944)

Differentiation from Other Viruses

Semliki Forest virus has been differentiated from the viruses of yellow fever, Bwamba fever, St Louis and Japanese B encephalitis viruses, eastern and western equine encephalomyelitis, and West Nile virus (Smithburn, Mahaffy, and Haddow, 1944) It is distinct from Bunyamwera virus (Smithburn, Haddow, and Mahaffy, 1946)

CHAPTER LI

COLORADO TICK FEVER

THIS DISEASE has been recognized in the Rocky Mountain areas of America since the end of last century, and has been called American mountain fever (Toomey, 1930–1) or Colorado tick fever (Becker, 1926, 1930). Modern interest dates from these papers of Becker and Toomey which clearly established the disease as an entity distinct from Rocky Mountain spotted fever. Topping, Cullyford, and Davis (1940) carried out an important study in Colorado. A general review is that of Florio and Stewart (1947), and Toomey gives an extensive bibliography to the earlier work.

CLINICAL FEATURES

A number of authors has described the clinical features which are very characteristic (e g, Becker, 1930, Toomey, 1930–1; Shaffer, 1935; Topping, Cullyford, and Davis, 1940, Collins, 1944; Florio and Stewart, 1947).

The incubation period is probably from 4–5 days Prodromal symptoms are rare and the onset is usually sudden The following symptoms are commonly observed: headache, chills, generalized myalgia, especially in back and limbs, photophobia, anorexia, and nausea. The throat and conjunctivae may be slightly congested.

The temperature soon reaches 102–104° F., where it remains for 48 hours The patient then apparently recovers for another 48 hours and the temperature is normal, but fever usually recurs. The second bout lasts for a further 2–3 days Convalescence is rapid, and fatalities or complications are unknown. There is not usually any marked reaction at the site of the tick bite, but an indolent ulcer may develop later.

Leukopenia is marked, and the total count may go down to 2000–3000 per c.mm. (Topping, Cullyford, and Davis, 1940, Collins, 1944; Florio, Stewart, and Mugrage, 1944, Florio and Stewart, 1947). All the leukocytes are absolutely reduced, except the monocytes, and there is a "shift to the left" in the polymorph series. On the 3rd–4th day after clinical recovery, the majority of cases shows an occasional large lymphocyte with basophilic bodies in the cytoplasm. These are spherical and measure about 0 5μ; they occur singly and in pairs and resemble nuclear material (Florio, Stewart, and Mugrage, 1944).

The virus is present in the serum of those naturally or experimentally infected, and can be recovered in the first or second bout of fever.

EPIDEMIOLOGY

The disease occurs mainly in Colorado, where there are 2 particular foci, one with the town of Boulder as center, and the other on the western slopes with Delta as the center, the flat prairie part of the state is free, but the disease has been reported from practically the whole mountainous region, it occurs also in Utah, Idaho, and Wyoming (Topping, Cullyford, and Davis, 1940)

The infection is contracted from the bite of ticks, and patients practically always give a history of being bitten by the wood tick *Dermacentor andersoni* Stiles, 4–6 days before the onset of illness The infection is transmitted transovarially in the tick, to at least the next generation of adults (Florio and Stewart, 1947). As in the case of Rocky Mountain spotted fever, the disease is commoner in adult males, who from their occupations are more likely than others to be exposed to ticks. The disease has a definite seasonal incidence, being found in spring and early summer before the hot, dry weather causes the ticks to disappear.

Colorado tick virus or a closely similar agent has been isolated from *D. variabilis* Say obtained from Long Island (Florio and Miller, 1948).

Differentiation from other Neurotropic Viruses

Tests were carried out with mixtures of Bunyamwera virus and antisera against other neurotropic viruses inoculated intracerebrally in mice Bunyamwera virus was found to be distinct from the following viruses. yellow fever, Bwamba fever, West Nile, St. Louis or Japanese encephalitis, eastern or western equine encephalomyelitis, or Semliki Forest (Smithburn, Haddow, and Mahaffy, 1946). Nor was any relationship shown to the viruses of Rift Valley fever, horse sickness, or to "Lot 6" virus

"Lot 6" Virus

This virus was isolated in the Entebbe yellow fever laboratory, but has not yet

REFERENCE

Smithburn, K. C., Haddow, A. J., and Mahaffy, A. F. (1946), *Amer. J. trop. Med.*, 26, 189

RELATIONSHIP TO OTHER INFECTIONS

Rocky Mountain Spotted Fever

Both diseases are tick spread, and occur in the same area, although RMSF has a wider distribution. Colorado fever is contracted in the upper timber reaches of mountain valleys, at an altitude above that where RMSF is endemic (Toomey, 1930–1). The two diseases are, however, quite distinct for the following reasons (Toomey, 1930–1, Florio, Stewart and Mugrage, 1944; Florio, Mugrage and Stewart, 1946) The clinical course of Colorado fever is different, with its intermittency, mildness, and rapid convalescence It is possible to contract both infections. Volunteers vaccinated against RMSF could still be infected with Colorado virus. Colorado immune serum did not fix complement with RMSF antigen (DeBoer *et al*, 1947).

Dengue

Clinically, the disease resembles dengue fairly closely, especially as regards the "saddleback" temperature, leukopenia, and short course, but there is no rash in Colorado fever. Reciprocal challenge tests performed on human convalescents have shown that an attack of one disease confers no protection against the other (Florio, Mugrage and Stewart, 1946, Florio *et al*, 1946, Pollard *et al*, 1946 *a*)

Other Viruses

Colorado immune mouse serum did not fix complement with antigens prepared from the following agents (DeBoer *et al*, 1947): eastern and western equine encephalomyelitis, murine typhus, American Q fever, St. Louis and Japanese encephalitis, or rabies

Cross neutralization tests in mice showed no relationship between Colorado virus and those of louping ill or Russian spring-summer encephalitis (Koprowski and Cox, 1946), nor was any relationship shown with Venezuelan, eastern or western equine encephalomyelitis, Japanese, St. Louis, LCM, yellow fever, dengue, or California viruses (1947 *a*).

Challenge experiments in man detected no relationship between Colorado and Bullis fevers (Pollard *et al*, 1946 *b*).

PROPERTIES OF THE VIRUS

To date, the observations point to *antigenic homogeneity of the various strains* (DeBoer *et al.*, 1947).

Experimental Transmission

The disease can be transmitted to *man* by the inoculation of human serum or virus passed experimentally, and the infection can be propagated in series (Florio, Stewart, and Mugrage, 1944, 1946, Florio *et al.*, 1946; Pollard *et al*, 1946*a*, Black, Florio, and Stewart, 1947). The experimental disease closely resembles the natural infection.

Hamsters are susceptible to intraperitoneal injection of human serum, and the infection can be passed in series using hamster serum (Florio, Stewart, and Mugrage, 1944, 1946; Koprowski and Cox, 1946; Black, Florio, and Stewart, 1947). There are no outward signs of illness, but the animals develop leukopenia, and round blue bodies up to 0.5μ in diameter may be found in the cytoplasm of atypical large lymphocytes Histologically, significant lesions occur only in the spleen (Black, Florio, and Stewart, 1947). Lesions are maximal on the 3rd day after inoculation They take the form of alterations in cellular type, and in the arrangement of the follicular lymphoid tissue, as well as a partial or complete disappearance of the normal well-defined follicular margin.

Mice can be infected. Koprowski and Cox (1946) established the virus in brown agouti and albino Swiss mice, using the cerebral route. Symptoms develop in 3–4 days, when the animals become hyperexcitable, and have ruffled fur, paralysis is rare. Virus can be found in the blood, but the maximum amount is found in the brain and cord The virus has also been transmitted to 21-day Swiss albino mice by the cerebral route by DeBoer *et al.* (1947). Eight-day mice are susceptible by the abdominal route (Koprowski and Cox, 1947 *a*)

Size, Filtration, and Cultivation

Florio, Stewart, and Mugrage (1946), on the basis of experiments in hamsters with collodion membrane filtrates, concluded that the agent passes through a membrane of 24 mμ pore diameter The size was estimated at 35–50 mμ by Koprowski and Cox, (1947 *a*) The virus passes Berkefeld N and Seitz EK filters (Koprowski and Cox, 1946).

Koprowski and Cox (1946) found that on yolk sac inoculation, virus generalized and could be recovered from the embryo, serial transfers could be carried out (see also 1947 *b*)

IMMUNITY

Active Immunity

One attack of the disease in man appears to immunize against a further infection Volunteers who contracted the disease 9–11 months before experimental infection, developed no, or only transient, symptoms on experimental inoculation (Florio, Stewart, and Mugrage, 1944)

Mice that survived inoculation with early passage virus were found to be resistant to challenge with active virus (Koprowski and Cox, 1946). Egg-adapted virus could also be used (1947 *b*)

Serum Antibodies

Complement fixation can be demonstrated between infected tissues and human or animal antiserum The antigen is best prepared by lyophilization of mouse brain and extraction with benzene, toluene, or dichlor-ethylene (DeBoer and Cox, 1946, DeBoer *et al*, 1947). In man, antibodies probably appear about 2 weeks after onset, and persist for as long as 3 years (DeBoer *et al*, 1947)

Hyperimmune sera, e g, for use in complement fixation tests can be prepared in mice by a course of peritoneal injections (DeBoer *et al*, 1947).

Gover, Reed, and Collins (1934) found that an undue incidence of respiratory conditions was associated with a subnormal mean temperature, especially in the autumn. To a lesser extent, the incidence of these conditions (at that season) was associated with a raised relative humidity, a lowered temperature range, and lessened s[illegible] weather during the warm season [illegible] than were changes in the cold season [illegible] raised the incidence of colds, namely: temperature range, morning dry bulb temperature, evening dry bulb temperature, [illegible] pressure.

2. *Other* [illegible] poor ventilation (Kler, 1945), [illegible] espert, 1944), food allergy (Coca, 1941, Brown *et al*, 1943), chronic [illegible] e, e g, Locke, 1939, Stock, 1946), the onset of menstruation (Kler, 1945) In industrial workers, colds are more prevalent in office than factory employees (Kler, 1945). Locke (1939, 1940) finds the incidence higher in those who react abnormally to tests involving the breathing of O_2 or 5 per cent CO_2.

CLINICAL FEATURES

We do not propose to waste time in describing in detail the straightforward clinical features of the common cold, which are so well known that only certain aspects need be considered. Thus, Townsend and Sydenstricker (1927), in the course of an extensive survey of respiratory infections in the United States of America, recorded the following relative incidence of symptoms running nose, 81 per cent., obstruction of nostrils, 44 per cent; sudden onset, 37 per cent; cough, 31 per cent., headache, 19 per cent, sore throat, aches in body or limbs, each 14 per cent; fever, 13 per cent, inflammation of eyes, expectoration, each 12 per cent.; constipation, 10 per cent, tightness of chest, 4 9 per cent., and chilliness, 3 4 per cent. Similarly, Van Volkenburgh and Frost (1933) found that nine-tenths of their cases had coryza, two-thirds a cough, half a sore throat, a quarter were confined to bed, and a quarter were febrile X-ray examination may detect transient pulmonary shadows (Kennedy, 1943).

Complications The common cold, itself harmless, may nevertheless give rise to various disorders which have serious consequences, such as sinusitis, otitis media, mastoiditis, and in consequence meningitis, acute bronchitis and bronchopneumonia, chronic bronchitis which may lead to emphysema and bronchiectasis, tonsillitis, and enlargement of the cervical glands Recording the complications of 1,388 cases of minor respiratory disorder, Van Volkenburgh and Frost (1933) obtained the foll[illegible] *per cent*, *adenitis*, 4 6 *per cent*, *sinusitis*, 2 8 per cent, oth[illegible]

[illegible] *re unlikely* to [illegible] statistics in support may be quoted Thus, [illegible] ry of some 2,500 American students He found that 23 per cent. had at least 4 colds a year, 60 per cent had 2 or 3, while only 17 per cent had not more than a single cold. For 2 years 484 persons were examined by Van Volkenburgh and Frost (1933). They found that the average was 3 attacks per person of minor respiratory disease. Of 685 adult male students studied by Townsend (1924) only 71 escaped a cold during the 5½ months of winter Smiley (1944) estimated the number of colds (without fever) in U S Naval personnel at 2500 per 1000 men

PATHOLOGY

[illegible] (1930) examined a number of biopsy specimens of nasal mucosa. In the [illegible]

CHAPTER LII

THE COMMON COLD AND MINOR RESPIRATORY ILLNESSES

KRUSE (1914) suggested, on the basis of experimental work, that the causal agent of the common cold was a filtrable virus Although the disease has all the appearances of a virus infection, little further progress was made until Dochez and his associates showed that the chimpanzee could be infected. Dochez's virus has not been widely isolated, and it appears possible that it is not the usual causal agent.

The clinical picture of the common cold is often characteristic enough, especially when afebrile; the term "nasopharyngitis, acute, catarrhal" may usefully be used (see Faust and Simmons, 1944). Trouble arises in differential diagnosis when the catarrhal symptoms are complicated by pyrexia ("feverish cold"). The term "*catarrhal fever*" *is often used for such cases, but this condition certainly includes* many infections that are not caused by the common cold virus (Ludwick and Jones, 1943, U.S. Naval Research Unit No. 1, 1944).

There is no doubt that a number of agents gives rise to symptoms and signs resembling those of the common cold. Thus, the Commission on Acute Respiratory Diseases (1947 *a*, *c*) *distinguishes between 5 mild respiratory illnesses as follows.*

1. The term "undifferentiated acute respiratory disease" (ARD) is applied to an acute febrile disease of short duration characterized by constitutional reactions or local respiratory symptoms, sufficiently severe to require hospitalization, and by epidemic occurrence in recruits in the winter. Diagnosis is made largely by exclusion of more obvious causes.

2 The features of "severe common cold" (SCC) are coryza, constitutional symptoms, and fever.

3. "Common cold" (CC) is characterized by coryza with little or no fever

4. "Bronchitis resembling atypical pneumonia" (Br-AP), is distinguished from atypical pneumonia (AP) by absence of consolidation

5. "Minor respiratory illness" (MRI) refers to a mild, usually nonfebrile, respiratory illness observed among recruits.

In addition, it is probable that the clinical picture of the common cold can arise in infection with viruses such as influenza and atypical pneumonia, and bacteria may also be responsible

A number of useful reviews of the literature are available (Thomson and Thomson, 1932, Browning, 1935, 1942, Stuart, 1938, Greenspan, 1943)

PREDISPOSING CAUSES

1. *The weather* While some have found that climatic conditions *per se* have little, or at most only very slight, effect, van Loghem (1928–9) has stressed the role of variations in the air temperature, falls increasing, and rises decreasing, the incidence of colds. Milam and Smillie (1931) found that a slight, but abrupt, drop in the atmospheric temperature coincided with the development of an epidemic Similar observations have been made by Brown *et al* (1945), and Kler (1945)

Many stress the importance of chilling, and often-quoted work is that of Schade (1926), who found that German soldiers exposed to wet and cold winds developed 4 times as many colds as those not so exposed

eating food prepared by a cook who was suffering from an acute cold Experiments of Hare and Mackenzie (1946) suggest that particles of secretion largely fall downward on to clothing; an important source of infection would be particles liberated later by shaking the clothing.

BACTERIOLOGY OF THE COMMON COLD

Needless to say, great interest has been taken in the bacteriological findings in cases of the common cold, and we can only refer to certain of the more important results (see Bloomfield, 1921 *a*, *b*.; Cooper, Mishulow, and Blanc, 1921; Valentine and Mishulow, 1921; Williams, Nevin, and Gurley, 1921; Jordan, Norton, and Sharp, 1923, Robertson and Groves, 1924, Shibley, Hanger, and Dochez, 1926; Blackburn *et al*, 1930, Hoyle, 1932, 1934, Thomson and Thomson, 1932).

1. *Examination in the acute stage.* Many workers have failed to find any specific organism, either in the nose or throat. The usual findings have been only the common throat organisms streptococci, staphylococci, pneumococci, influenza bacilli, *Micrococcus catarrhalis*, and so forth Generally there has been no predominant organism, and it has been impossible to incriminate any one more than another. During the early stages of colds, there may be a diminution in bacterial content as compared with the state of affairs either in health or during the later stages of the illness. In the purulent stage, bacteria are usually increased in number.

However, a number of authors has regarded bacteria as the primary cause of colds (see in particular Schroder and Cooper, 1930, Thomson and Thomson, 1932; Hoyle, 1932, 1934). These workers usually examined selected persons at frequent intervals During health probably only small numbers of pathogens were isolated, but on repetition during an attack of coryza profuse growths of one or more pathogens were obtained, and to these was attributed an etiological rôle. The organisms particularly incriminated by these workers were influenza bacilli and pneumococci Probably streptococci, *M catarrhalis*, and other organisms may also be responsible

With regard to anaerobic bacteria, it was at one time thought that these might be of etiological importance in colds However, as they have been found to occur frequently in the perfectly normal upper respiratory tract (Mills, Shibley, and Dochez, 1928), and in various other diseases (Burky and Freese, 1931), it is unlikely that their presence is of any consequence (see also Noble and Brainard, 1932).

2. *The bacteriology of colds in children.* In infants Kneeland (1930) could find no evidence that bacteria were responsible for first colds In recurrent colds of

induce an attack of cold

They noted that colds tended to be frequent in the autumn, these colds were of mild nature and unassociated with any change in the bacterial flora At this time of year there was a low carrier rate of pathogens, but after the outbreak this rose In mid-winter, when carriage of pathogenic organisms had become very frequent, a severe type of cold prevailed, and was of a different nature from the mild autumnal type These colds affected particularly children from 8 to 14 months old

These studies led the authors to suggest that the virus of the common cold *per se* caused the earlier, milder attacks. The effect of the virus was to increase the susceptibility of the tissues to pathogenic bacteria, and the severer and later colds were due mainly to the presence of these.

3 *The bacteriology of colds in isolated communities.* Burky and Smillie (1929) studied the nasopharyngeal flora in Labrador, and in southern Alabama, obviously places with two very different climates. In Alabama they recorded an increase in

or may occur in a zone next to the surface. The necrosis may extend deeply. By the third day, almost all the columnar cells have disappeared, and some of the stellate cells close to the basement membrane also slough.

After the acute stage, the remaining cells proliferate and form a syncytium. Eventually the cells lengthen and again appear columnar.

The secretion in the first few hours is watery, and contains comparatively few cells. Sometimes within the first 24 hours living ciliated cells appear. They are more numerous during the 2nd day, and disappear after the 3rd, when the secretion is purulent. They may disappear in a matter of a few hours. The deeper epithelial cells, polyblasts, and polymorphs appear on the 2nd day and become rapidly more numerous. The polymorphs are the predominant cells after a few days.

EPIDEMIOLOGY

Colds occurring in the tropics are said to be milder than those of more temperate lands. Studying Eskimos, Heinbecker and Irvine-Jones (1928) found that colds broke out within 72 hours of the arrival of an exploring party. The infection spread very rapidly to involve almost the whole village. After recovery, colds were not again experienced until a further visit of the explorers. Paul and Freese (1933) on Spitzbergen found that colds broke out on the arrival of the first boat of the year and rapidly spread through the population. Similar observations have been made in an Eskimo community (Høygaard, 1939), and on a Pacific island (Norris, 1944).

The Spread of Colds

By cases. Cases are the main factors in the dissemination of colds, and the filtrable virus has been recovered from the nasal and throat secretions, as have the various pathogenic organisms suspected of bearing a causal relationship to the condition. It is thus certain that the means of spread is by infected droplets. Colds are probably first infective late in the incubation period and for a day or so of the coryzal stage. Thus it has been recorded that two chimpanzees caught colds from a worker who, although appearing well at the time, developed a cold on the following day (Long, Bliss, and Carpenter, 1932).

It is a matter of common knowledge that colds are highly contagious, but exactly what mechanisms are responsible for their spread under natural conditions is hard to determine. For instance, Kerr and Lagen (1933–4, 1934) exposed a number of presumably susceptible volunteers to a person suffering from an acute cold. The volunteers and the case were segregated in a special isolated room, and there was every facility for contact infection. However, none of the volunteers contracted the infection. Thomson and Glazebrook (1941) found that an epidemic failed to develop in a community of naval trainees although conditions were very favorable to spread, and tonsillitis was in fact epidemic.

By carriers. There are few experimental observations dealing with the question of carriers of the causal agent. In temperate lands it would appear probable that such carriage does occur, for the following reasons. Colds frequently develop after exposure to cold, wet, or other adverse influence, without any known contact with a case of the disease. This suggests that the causal agent has lain latent in the nose or throat of the victim and has been awakened into activity. Moreover, even without exposure to adverse influences, colds frequently develop in the absence of any known exposure to a case of the disease, this can be explained by postulating either autogenous infection, or infection from an outside apparently healthy source. Thirdly, and less speculatively, it has been recorded that after the arrival of healthy explorers, Eskimos have developed colds, also, on Spitzbergen colds break out on the arrival of the first boat of the shipping season (*vide supra*). These observations strongly suggest the existence of carriers of the causal agent.

By fomites. It is probable that colds may be spread by fomites. Thus, Bliss and Long (1933–4) found that an otherwise isolated chimpanzee developed a cold after

There is thus abundant evidence that the causal agent of some colds is filtrable. We shall first describe the characters of the virus isolated by Dochez. We are not, as yet, prepared to accept this agent as the cause of all colds, although it is probably responsible for some.

Properties of the Common Cold Virus (Dochez)

Infection in chimpanzees.

Dochez and his coworkers have shown that the ape can be readily infected with material from human colds (see, e g, Dochez, Shibley, and Mills, 1928–9, 1930, Shibley, Mills, and Dochez, 1930, see also below).

1 *Natural infection* Natural infection with colds may arise quite readily, thus, attendants in zoological gardens report that colds are quite common among apes In experimental laboratories also, these animals are very readily infected from human beings, unless rigorous quarantine is carried out.

2. *Experimental infection.* Infection is readily initiated by instilling about 1 c.c. of filtered nasal secretion from human cases of common cold. The disease develops after about 36 to 48 hours' incubation period. The animals are sluggish, and the eyes appear puffy; there is a mucoid secretion in, and obstruction of, the nasal passages. The animal coughs and sneezes, and after a few days the nasal secretion becomes mucopurulent.

3. *Control observations.* Inoculation of chimpanzees with broth and other fluids has never produced such manifestations of infection, further, Shibley, Mills, and Dochez (1929–30) have shown that intranasal inoculation with filtered nasal washings of normal persons has no effect.

4 *The rôle of bacteria in experimental infection.* It has been reported that the nasopharyngeal flora of chimpanzees in health is very similar to that of man (Dochez, Shibley, and Mills, 1930). However, with the onset of experimentally induced colds the same authors found a change to occur in the flora, Pfeiffer's bacillus was easily recognized, and from throat cultures pneumococci could be isolated.

Further, Dochez, Mills, and Kneeland (1932–3) found that an interesting change might occur after chimpanzees had been inoculated intranasally with their cold virus Strains of *B influenzae* which, in health, were rough and avirulent now changed into the "S" or virulent form

Infection in other animals.

Edwards (1935–6) reported that hedgehogs might develop catarrh after nasal inoculation of infective human filtrates. It appears that very trivial lesions may be produced in mice (Chapman and Hyde, 1940, Powell, Sparks, and Clowes, 1940).

Filtrability and cultivation.

The agent has been found to pass all grades of Berkefeld filter (see, e g, Kruse, 1914, Foster, 1916, Shibley, Mills, and Dochez, 1930, Dochez, Shibley, and Mills, 1930, Long *et al*, 1931). It also passes a Seitz filter (Dochez, Mills, and Kneeland, 1930–1, Long *et al*, 1931)

It has been shown that the virus of the common cold can be cultivated *in vitro* (see Dochez, Mills, and Kneeland, 1930–1, 1931, 1931–2, 1936, Powell and Clowes, 1931–2, Powell, Sparks and Clowes, 1940).

The virus is grown in chick embryo and buffered bouillon or Tyrode's solution, according to the technique elaborated first by the Maitlands and later by Li and Rivers (see Ch XII). The cultures should be transferred at 2- to 3-day intervals to obtain the best results.

Virus grown in tissue culture is still able to produce colds in human volunteers on suitable inoculation. Thus, Powell and Clowes found that the 27th generation

the number of Pfeiffer's bacilli and pneumococci in association with colds. The bacterial flora [illegible] Indies, was ex[illegible] much less frec[illegible] found that th[illegible] and Alabama They found no change in the flora in those who developed colds The nasopharyngeal flora of dwellers on Spitzbergen was examined by Paul and Freese (1933). They did not find any evidence that the bacterial flora was concerned in the causation of colds With the possible exception of Burky and Smillie's work, it is thus evident that these studies have done nothing towards establishing bacteria as the cause of the common cold.

4 *Bacterial vaccines in the prevention of colds.* Much has been written on the subject of the prophylaxis of colds by vaccination. Vaccines, either stock or autogenous, have usually contained staphylococci, streptococci, *Micrococcus catarrhalis*, Pfeiffer's bacilli, and other organisms.

There is no doubt that many have expressed satisfaction with their results (see e.g., Thomson and Thomson, Veasey, 1941; Walsh, 1940, 1941; Herron, 1943). Such vaccines may be injected subcutaneously, intradermally, orally, or nasally. There has, however, been a number of investigations, some on a large scale, which entirely failed to show that vaccines have any prophylactic effect (von Sholly and Park, 1921, Ferguson, Davey, and Topley, 1927, Wallfield, 1937, Diehl *et al*, 1938, Siegel *et al*, 1943, Council on Pharmacy and Chemistry, 1944; Cowan and Diehl, 1944, McGee *et al.*, 1944, Bourne, 1946).

THE VIRUS THEORY OF THE COMMON COLD

Early Experimental Observations

Negative transmission experiments. Certain authors have failed in their efforts to transmit the infection by filtrates of nasal or nasopharyngeal secretions (e.g., Williams, Nevin, and Gurley, 1921, Robertson and Groves, 1924). The inoculations were given intranasally to human volunteers

Kerr and Lagen (1933–4, 1934) found that intraconjunctival inoculation of infected nasal secretion failed to transmit the disease. Further, they failed to transmit the disease by placing a case in an isolated room with susceptibles. Despite these negative results, numerous authors have succeeded in transmitting the infection

Positive transmission experiments. Kruse (1914) was probably the first clearly to suggest the possibility of a filtrable virus being the cause of colds He produced infection in human volunteers by inoculation with filtered nasal secretion of coryzal cases Later Foster (1916, 1917) prepared Berkefeld filtrates from the nasal secretion of cases of colds, and 90 per cent of volunteers injected with these filtrates developed symptoms within 8 to 30 hours Dold (1917) also obtained positive inoculation results with filtrates Olitsky and McCartney (1923) found that the filtered throat washings of cases of colds could transmit the infection to human volunteers By means of Berkefeld filtrates of the nasal secretion of cases, Dochez and his colleagues were able to infect human volunteers (Shibley, Mills, and Dochez, 1930, Dochez, Shibley, and Mills, 1930) Andrewes and Oakley (1931–2) are also reported to have infected human volunteers

Human inoculation experiments were likewise successfully carried out by Long, using as inocula filtrates of secretion (Long and Doull, 1930–1, Long *et al*, 1931) The infection was passed through a number of persons in series Walker (1931–2) has pointed out that care is needed in interpreting the results of inoculation tests, volunteers may imagine that they have actually developed a definite cold when they have been inoculated intranasally only with control noninfective material

More recently positive results have been obtained by Andrewes and his group, and by the Commission on Acute Respiratory Diseases (see below)

ogous SCC filtrate developed illnesses, although these were somewhat milder than on the first occasion.

9. No cross resistance could be demonstrated between the causal agents of ARD and the common cold.

10. In further experiments, it was confirmed that primary atypical pneumonia could be induced by means of bacteria-free filtrates Previous infection with ARD and SCC filtrates did not give any resistance to AP

11. To summarize the work reported in these two papers, it appears that at least 2 filtrable agents may induce minor respiratory illnesses in man, and these viruses are probably distinct from the causal agent of primary atypical pneumonia Pollard and coworkers have reproduced colds with Seitz filtrates of nasal washings stored at −20° C for up to 115 days (Pollard, Dernehl, and Caplovitz, 1948).

IMMUNITY TO THE COMMON COLD

Chimpanzees recovered from natural or experimental cold infection are resistant to reinfection for 3 to 4 months (Dochez, Shibley, and Mills, 1930). There is dubiety as to whether immunity follows infection in man, but probably there is a transient resistant state. Thus the observations of Paul and Freese (1933) at Longyear City, Spitzbergen, showed that immunity followed an attack and lasted for 3 to 7 weeks Investigating the disease in a community of naval trainees, Thomson and Glazebrook (1941) could find no evidence of immunity resulting from overt or subclinical attack.

PREVENTION AND SPECIFIC TREATMENT

In institutions, the incidence of colds can be lowered by spraying with propylene glycol (Harris and Stokes, 1943). A number of reports has alluded to the lowered incidence of respiratory infections, including presumably colds, by measures directed to lessening dust, ultraviolet irradiation is also effective. It has been claimed that the incidence can be lowered by periodical injections of gamma globulin (Adams and Smith, 1946). There is no evidence that the administration of vitamins lowers incidence (Cowan, Diehl, and Baker, 1942; Dahlberg, Engel, and Rydin, 1942)

Preliminary reports on the value of patulin in treatment (Raistrick *et al*, 1943) have not been confirmed (Patulin Clinical Trials Committee, 1944; Stansfeld, Francis, and Stuart-Harris, 1944) Sulfonamides do not shorten the course of the disease, but control secondary invaders, and lessen the incidence of complications (Cecil, Plummer, and Smillie, 1944, Faust and Simmons, 1944).

produced severe colds in 75 per cent. of inoculated persons Andrewes and Oakley (1931–2) are reported to have failed to infect London volunteers with Dochez's cultures sent from America. Dochez, Mills, and Kneeland (1938), in a preliminary series of experiments, found that immunization of human beings with tissue culture virus was ineffective.

Only trivial lesions result from chorio-allantoic inoculation (Kneeland, Mills, and Dochez, *1936–7*; Hyde and Chapman, 1937; Peragallo, 1938, Chapman and Hyde, 1940)

Preservation.

To preserve the virus for some length of time various procedures may be adopted (Dochez, Mills, and Kneeland, 1930–1, 1936):

(*a*) Nasopharyngeal washings may be frozen and desiccated *in vacuo*, when virulence is preserved for at least 4 months

(*b*) Nasopharyngeal washings, kept anaerobically in the refrigerator (with cysteine added), remain virulent for at least 13 days.

(*c*) *If gum acacia is mixed with infected tissue culture, then frozen and dried in vacuo*, virulence is preserved

Later Experimental Observations

The British Medical Research Council is sponsoring experiments conducted by Dr. C. H. Andrewes on human volunteers, and this group has shown that there is no doubt that mild colds can be transferred by means of filtrates (see Andrewes *et al.*, 1947, *Brit. med J*, 1947, *1*, 650) The agent can be stored for some months at −76° C. (Fulton, 1947).

Some evidence pointing to growth in the allantoic cavity has been obtained (Pollard and Caplovitz, 1947, 1948, Topping and Atlas, 1947)

Experiments have been carried out by the U.S. Commission on Acute Respiratory Diseases (1947 *a*, *b*, Dingle, 1947).

1. As a control, a number of volunteers were first inoculated with filtrates prepared from their own nasopharyngeal washings No illness was produced

2. Of 14 volunteers inoculated with filtrate from a case of ARD (see above), 12 developed minor respiratory illness, and 2 remained well. Symptoms were first *observed in 9 persons on the 5th–6th day after inoculation*

3. Next, 14 volunteers were inoculated with filtrate from a case of SCC, and 9 developed illness within 24–48 hours. The features were those of "common cold," and could be distinguished from those following the ARD inoculation

4 Some 10 volunteers were given filtrate from a case of common cold Six developed common colds. The onset of the illness occurred within 4 days of inoculation

5. A group of 10 volunteers was given filtrate from a case of Br-AP, 4 developed minor respiratory illnesses, without fever None of the illnesses was as severe as that in the donor of the inoculum

6. There were no consistent alterations in bacterial flora, serological tests, or tests for influenza virus in these groups

7. Discussing these results, the Commission point out that only 2 types of ill- [illegible] -s of the various inocula The first type, [illegible] by pharyngeal involvement, and an in- [illegible] type, induced by CC and SCC filtrates, was characterized chiefly by coryza, and an incubation of 24–48 *hours* *The* evidence suggested that the causal agent of the common cold is a virus, ARD is probably caused by a distinct virus

8 None of 6 individuals receiving ARD filtrate 3 weeks after a previous inoculation developed evidence of respiratory illness, 4 of 5 men inoculated with homol-

Virus was recovered from the conjunctival secretion by allantoic inoculation There were no general symptoms, and there was no increase in antibody. In the second case, a laboratory assistant complained of slight conjunctival irritation, with a mild regional adenitis. Virus was recovered from the tears. Workers in Palestine have also described conjunctivitis due to laboratory infection, as well as small outbreaks in persons preparing infected poultry for the table (Shimkin, 1946; Yatom, 1946).

Some Properties of the Virus

The virus was found to measure 80–120 mμ as determined by ultrafiltration, whereas that of fowl plague measure 60–90 mμ (Burnet and Ferry, 1934).

Purified preparations examined in electron micrographs may show sperm-like forms (Bang, 1946, Cunha *et al*, 1947). However, if, after centrifugation, the deposit is suspended in water instead of saline, the virus shows a preponderance of spherical forms; on adding saline, the filamentous form is assumed, this change can be prevented by partial inactivation with formaldehyde, mustard gas, or gentle heat (Bang, 1947)

The infection can be transmitted to poultry and pigeons by inoculation of filtrates prepared from the organs of dead birds (Doyle, 1927).

Mice may show a consolidation of the lungs when inoculated intranasally on a

tion of virus inter-

The virus can be

The virus grows in the egg, and can be inoculated by the amniotic and allantoic routes, and on the chorio-allantois (Burnet and Ferry, 1934; Iyer and Dobson, 1940, Burnet, 1942; Burnet, 1943, Lush, 1943, Anderson, 1946, Beveridge and Burnet, 1946, Burnet and Anderson, 1946, Cunha *et al.*, 1947).

Foci are developed on the chorio-allantois, especially with more dilute preparations, it becomes abnormally moist and edematous. Small petechial hemorrhages are seen. There is patchy ectodermal proliferation, followed by vacuolation and necrosis (Burnet and Ferry, 1934). The embryo dies from hemorrhagic encephalitis, hemorrhages are also found in the pectoral muscles, skin, and intestines (Burnet, 1942, 1943). On chorio-allantoic passage, the virus becomes less virulent for fowls (Iyer and Dobson, 1940).

After amniotic in

is turbid, and shows

found in the embry

Virus grows well in the allantoic fluid on intra-allantoic inoculation (Burnet, 1942).

A fatal infection with hemorrhagic lesions follows intravenous inoculation (Beveridge and Burnet, 1946).

The virus can be titrated by inoculation on the chorio-allantois, in the amniotic or allantoic cavity, or by chick cell agglutination *in vitro*. The intravenous route can also be used (Hanson, Winslow and Brandly, 1947)

The virus is resistant to glycerin (Burnet and Ferry, 1934). The maximal stability occurs between pH 4 and 11 (Moses, Brandly, and Jones, 1947).

Cunha *et al* (1947) have purified the virus by centrifugation, and found that it is a complex of protein (approx 67 per cent.), lipid (about 27 per cent.), and a small amount of nucleic acid, some of which is of the desoxypentose type

Hemagglutination Produced by NDV

Newcastle virus causes agglutination of chick and other red cells (see Ch LXI), as has been shown by Burnet, his collaborators, and others (Burnet, 1942; Clark

CHAPTER LIII

NEWCASTLE DISEASE[1]

Original Description

DOYLE (1927) first described the features of a virulent infection of poultry that occurred in 1926. The first outbreak was near Newcastle-on-Tyne, and other districts were involved later. The incubation period was 4–11 days The disease resembled, but could be differentiated from, fowl plague The mortality was about 100 per cent. and the disease was evidently spread by contact.

A filtrable virus was isolated from the body fluids, organs, and excretions.

Geographical Distribution

Outbreaks of Newcastle disease, due to immunologically identical strains have occurred in many parts of the world, for example Dutch East Indies, Philippines, India, Ceylon, Korea, Japan, Kenya, Palestine, Italy, Germany, and the U. S. A (Doyle, 1935, Beaudette, 1946; Brandly *et al*, 1946).

The disease occurred in a poultry flock in Victoria in 1930, and became widespread in Melbourne, it reappeared in 1932 (Albiston and Gorrie, 1942). Fowls were chiefly affected, but also turkeys. Ducks and geese showed a marked resistance. The death rate of the natural disease varied from 50–100 per cent The fowls showed dullness, somnolence, mouths sticky with exudate, diarrhea, and final prostration and twitchings, some cases of chronic infection were seen Postmortem examination showed generalized hemorrhages, ecchymoses in the proventriculus, and intestinal submucous hemorrhages. The infection could be transmitted artificially. Tests performed by Doyle showed that the agent was a strain of Newcastle disease virus (NDV).

The condition of avian pneumo-encephalitis of young chickens first found in California but now elsewhere in the U S A, and the disease of mature birds known as "chicken flu," is caused by a filtrable virus immunologically identical with that of NDV (Beach, 1944, 1946).

The methods of laboratory diagnosis in suspected outbreaks are discussed by Beaudette (1946) and Osteen and Anderson (1948).

During World War II the disease was intensively studied by workers in the U S. A and much important information obtained (Beach, 1946, Brandly *et al*, 1946).

Human Infection

Burnet (1943) described an infection due to squirting of infectious allantoic fluid into the eye The next morning there was an acute conjunctivitis, and the right preauricular gland was swollen and tender There was a headache, slight feeling of chilliness, and discomfort The following day there was an improvement The inflammation subsided in 2 weeks

The virus was recovered by amniotic inoculation Antibody could be detected in the convalescent serum by a chick-cell agglutination test, and by the inoculation of serum-virus mixtures on the chorio-allantois

Two further laboratory infections have been described by Anderson (1946) In one case, a mild bilateral conjunctivitis followed the splashing of virus in the face

[1] Newcastle disease primarily affects birds, man is only rarely infected Consequently, we shall discuss the properties of the virus only briefly, and with particular reference to its biological relationship to influenza virus

may agglutinate NDV-treated cells, and that this phenomenon is not specific (Evans and Curnen, 1948).

Action of anti-Rh sera.

When human cells were treated with NDV, only the Rh positive cells, containing D Rh antigen, were agglutinated by the incomplete anti -D Rh antibody (Chu and Coombes, 1947).

IMMUNITY

It has proved possible to immunize poultry with vaccines produced in the egg (Beach, 1946). Hamster-adapted virus has also been used (Reagan *et al*, 1948).

Antisera can be produced in rabbits and ferrets by injections of the virus (Burnet, 1942). Antibodies develop in the sera of fowls injected with formolized virus, followed by live virus, and in the sera of guinea-pigs given intravenous or intracardiac injections (Burnet and Anderson, 1946). Antibody is found in the sera of human convalescents (Burnet, 1943).

Antibody can be titrated by CCA-inhibition tests (Lush, 1943; Burnet and Anderson, 1946, Florman, 1947, or by cells with serum (Burnet and Anderson, the view that the antibody titrated by cells treated with NDV are agglutinated to a lower titer by antisera to swine virus.

Antigenic Relationship to Other Viruses

Influenza Despite their similar biological properties, serological tests show no antigenic relationship between the two agents (Burnet, 1942) The morphology shown by the electron microscope (see above) is certainly different from that of influenza virus It seems difficult to believe, however, that the similarities shown by the hemagglutination reaction do not indicate a close relationship between the two agents

Mumps. As has been explained, the hemagglutination reaction shows that the two viruses have similar properties, and fall in the same linear series Cells treated viruses Cells treated with mumps a reduced titer (Burnet, 1945) hought that the disease is only a ιle (1927) differentiated the two agents by cross immunity tests, and found that pigeons could be infected with Newcastle, but not fowl plague virus The two agents can be differentiated by many biological properties, including size, and the appearance of infected eggs (Burnet and Ferry, 1934). Lush (1943) using CCA-inhibition tests, found no relationship between the two agents

Other viruses Beach (1944) has shown that the viruses of avian pneumo-encephalitis of young chickens and "chicken flu" are apparently immunologically identical with NDV.

and Nagler, 1943, Lush, 1943, Burnet, 1945; Burnet *et al*, 1945; Burnet and Anderson, 1946; Burnet, McCrea, and Stone, 1946; Chu and Coombes, 1947, Cunha *et al.*, 1947, Florman, 1947, 1948; Hanson, Winslow, and Brandly, 1947). In this work, the following properties of the NDV agglutinin have been described.

1. Agglutination is best recognized by studying the pattern of the cell sediment, rather than by clearing of the supernatant.

2. Human cells are not quite so readily agglutinated as fowl cells, but otherwise behave similarly.

3. Heating and formalin render NDV noninfective, but hemagglutinating capacity is retained.

4. Seitz filtration causes marked loss of infectivity, while the hemagglutinating titer is hardly lowered, suggesting that particles smaller than the virus are responsible for some of the hemagglutination. Cunha *et al.* (1947), however, found that infectivity and hemagglutinative activity were correlated with the presence of virus particles.

5. Agglutinated cells rapidly elute virus, and thereafter become completely inagglutinable or "stabilized." Thus, when tubes containing fowl cells agglutinated by NDV at room temperature are shaken, the cells usually fail to reagglutinate When such cells are washed and resuspended, they form a stable suspension Elution and stabilization can also be shown by adding human cells to serial dilutions of virus, and holding at 37° C Deposition is almost complete at 1 hour If the rack is then shaken and allowed to stand, by the end of the 2nd hour, all tubes containing over about 40 agglutinating doses show stabilized inagglutinable cells. At 4° C, elution does not take place so quickly.

6. Cells treated with ND virus in this way, and made up in the form of a stabilized suspension, can no longer be agglutinated by the homologous virus or by mumps virus, but are agglutinable by influenza viruses. This is because mumps, NDV, and influenza viruses can be arranged in a linear series, such that when red cells are treated with virus, and then exposed to the action of other viruses, the cells are not agglutinated by the virus used to treat them, or by viruses preceding this one in the series, but are agglutinated by viruses later in the series (see Ch. LXI).

7 Florman (1947) recommends the performance of hemagglutination tests at 4° C. instead of room temperature.

Agglutination of NDV-treated cells by sera.

1 Cells treated with NDV can be agglutinated by specific antisera prepared in animals, and this can be used as a means of titration of antibody.

2. Nearly all normal human sera agglutinate human red cells treated with NDV, to a titer *below 1, 120 This phenomenon is probably related to Thomsen's panag*glutination of red cells by bacteria (Burnet and Anderson, 1946, Chu and Coombes, 1947).

3. The majority of sera from cases of infectious mononucleosis agglutinates NDV-treated cells to a titer over 1, 120, fowl, guinea-pig, and human cells can be used (Burnet and Anderson, 1946)

4. The sensitizing factor in NDV which renders red cells susceptible to agglutination by sera from cases of infectious mononucleosis is probably not ND virus itself. The factor is probably adsorbed to the surface of the red cell

5. There are 3 possible explanations for this agglutination of NDV-treated cells by mononucleosis sera (*a*) The etiological agent of infectious mononucleosis is related antigenically to NDV (*b*) The relationship is accidental, and analogous to that between *Rickettsiae* and *Proteus* (*c*) A labile globulin is developed in the serum in infectious mononucleosis, and this by some accident of molecular structure reacts with NDV as well as sheep red cells (Burnet and Anderson, 1946)

6. Later work suggests that the sera of patients suffering from several infections

CHAPTER LIV

PANDEMIC INFLUENZA (1918–19)

Introduction

INFLUENZA is a disease which has been known for several centuries, although it is not always certain that the diagnosis in some of the earlier outbreaks is beyond suspicion. There was no unanimity regarding the causal agent until recently, when, in 1933, British workers reported the isolation of a filtrable virus This agent has now been isolated in many parts of the world and well-nigh universally accepted as the etiological agent. Prior to 1933 many believed Pfeiffer's bacillus to be the causal agent, it is now usually believed, however, that its rôle is secondary rather than primary.

The world has been visited by a number of comparatively well-authenticated pandemics of influenza since about the beginning of the 12th century In comparatively modern times such pandemics occurred in 1847–8, 1889–91, and 1918–19. Those who are interested in the history of influenza should consult the works of Hirsch (1883),[1] Creighton (1891, 1894), and Townsend (1933). This chapter will be concerned almost entirely with describing the 1918–19 pandemic, which actually resembled the 1889–91 outbreak closely. This 1918–19 outbreak was experienced in all parts of the world The disease had a high attack rate, pneumonic complications were common, and these cases had a high mortality rate The disease occurred in 3 main waves, spring to summer 1918, autumn 1918, and spring 1919. Influenza has not occurred in pandemic form since this period

Much literature has been published on influenza, in particular from 1918 to 1920, and since 1933. A number of excellent monographs has appeared, which should be consulted by those who desire further information on, and references to, work carried out prior to the isolation of the virus in 1933 (e g, *Medical Supplement*, 1918, Ministry of Health, 1920, Crookshank, 1922, Jordan, 1927, Scott, 1929, Thomson and Thomson, 1933, 1934, Burnet and Clark, 1942). The work of the Thomsons is the most outstanding and complete, as over 4,500 papers are reviewed

CLINICAL FEATURES OF PANDEMIC INFLUENZA

Premonitory illnesses In 1915 influenza was prevalent in the United States, in Great Britain, and in later years in other countries, but these outbreaks did not spread widely During 1917, British authors drew attention to the frequent occurrence of an unusual condition which appeared to be almost a "new disease"—purulent bronchitis (Hammond, Rolland, and Shore, 1917, Abrahams *et al.*, 1917, see also 1919) This condition occurred particularly in troops in the Aldershot Command (England) and in France, and was characterized by an abundance of mucopurulent to frankly purulent sputum, and cyanosis. *B influenzae* was isolated in many cases, but usually associated with other throat organisms. The disease did not show any tendency to spread among the populace, but it was of interest as it had many features of true influenza

Incubation period Countless observations proved this period to be 24 to 48 hours.

Onset The onset of the disease was characteristically sudden There might be a single case in a community on a given day, every one else feeling in perfect health, then, on the next day thousands might be affected Many a person was hit-

might be a degree of absolute lymphocytosis. Leukocytosis might be observed in cases complicated by pneumonic conditions

BACTERIOLOGY OF PANDEMIC INFLUENZA

Needless to say, influenza attracted the widest interest, and countless workers reported the results of their bacteriological investigations (e g, in *Great Britain*: Influenza Committee, 1918, Fildes, Baker, and Thompson, 1918, Hopkins, 1918–19, McIntosh, 1918, 1922, Whittingham and Sims, 1918, Logan, 1919, 1921, Fildes and McIntosh, 1920, Scott, 1922; Donaldson, 1922, in *France*: Influenza Committee, 1918, Tytler, Janes, and Dobbin, 1919, Gibson and Bowman, 1919, in the *United States*: Blanton and Irons, 1918, Camp Lewis Pneumonia Unit, 1919, Park, 1919, Pritchett and Stillman, 1919, Stone and Swift, 1919, Williams, 1919, Opie *et al.*, 1919 *b*, in *Germany*: Bernhardt, 1918, Dietrich, 1918, Simmonds, 1918, in *India*: Greig, 1920–1) Those who desire fuller information should consult Thomson and Thomson (1933, 1934) or Jordan (1927).

Specimens were usually taken from throat swabs, garglings, or sputa. *B. influenzae* * was frequently found in such specimens, either in pure culture or more frequently along with the usual throat flora In fact, certain observers found the organism in over 80 per cent. of cases A fuller discussion of the rôle of *B influenzae* is found below

A variety of organisms was isolated by postmortem lung culture The severest lesions were produced by *B. influenzae*, *Pneumococcus*, hemolytic streptococcus, and *Staphylococcus aureus* In certain cases nonhemolytic streptococci were isolated (e g, by Blanton and Irons, 1918, Gibson and Bowman, 1919) *Neisseria* organisms were also isolated, some at least being true meningococci (Fletcher, 1919).

With regard to serological observations, it was reported that the sera of influenza convalescents fixed complement with influenza bacilli as antigen, and that agglutination also occurred (e g, Sobernheim and Novakovic, 1918, Gibson and Bowman, 1919, Gay and Harris, 1919, Rapoport, 1919, Scheer, 1919, Cooke, 1920, McIntosh, 1922, Sharp and Jordan, 1924) The agglutination was probably not specific, as serum of measles convalescents was also found to agglutinate *B influenzae* (Sharp and Jordan).

MORTALITY

Although the total number of deaths throughout the world was enormous, the average mortality rate was not much over 3 per cent. Death was invariably produced by some respiratory complication French (1920) found that about 20 per cent of cases developed pneumonia in the 2 later waves, and of these nearly half died In the United States of America it was estimated that 550,000 deaths occurred, and in Great Britain 220,000 In the whole world the total death rate probably amounted to over 20 million (Jordan, 1927) The majority of deaths occurred in persons between 15 and 45, especially in the later waves This feature was unusual as previously influenza, even in pandemic form, had tended to show maximum mortality figures for those over 60 years of age The tendency to cause a fatal result in young adults was one of the main characteristics of pandemic influenza in 1918–19 The pandemic increased the total death rates, deaths from respiratory diseases, and deaths from diseases of various other systems, such as the heart.

PATHOLOGY

The Respiratory System

Virtually every fatal case of influenza in 1918–19 presented evidences of pulmonary involvement, the other organs of the body being only slightly affected.

* In this chapter we retain the old name, *B influenzae*, rather than *Haemophilus influenzae* which has come into general use only since the days of pandemic influenza.

erally rendered acutely ill within an hour or so of first feeling unwell. Rigors were often experienced at the onset, headache and *fever soon developed*, while *epistaxis* was a common finding. In another type of case the disease was ushered in with intense congestion of the nose, pharynx, larynx, trachea, and conjunctivae (see Bloomfield and Harrop, 1919). In certain cases the illness developed as a sudden increase in severity of a preexistent coryza, headache, or cough.

Course. There was considerable difference between the course of the cases seen in the summer of 1918 and those seen in the 2 later waves, pneumonia developed in about 20 per cent. of the later cases but was very rare in the earlier. We will record the clinical features as described by French (1920), who saw some thousands of British cases during the 3 waves, and was able to correlate his clinical and pathological findings.

Cases in the first wave This type of illness was often known as 3-day influenza The onset was rapid, the patient being seized with intense lassitude, the temperature remained raised for about 2 days to fall by the third There was intense headache and general aching, the face was flushed, the tongue furred, the throat sore and red, and the voice husky. The patient was usually well within a week, and complications were rare.

Cases in the later waves. French estimated that about 80 per cent. of the cases seen in autumn 1918 and spring 1919 were comparatively mild, were devoid of complications, and resembled those seen earlier. The remaining 20 per cent, however, suffered from pneumonia and nearly half died

Pneumonic cases. The pneumonia of influenza might develop in various stages of the illness (French)

(*a*) After a day or so of mild illness the patient rapidly became worse and showed evidence of lung involvement.

(*b*) Some cases were stricken with pneumonia from the onset.

(*c*) Pneumonia developed late in some patients, after about a week of comparatively mild influenza.

(*d*) In some cases the pneumonic process developed later, during convalescence

Pain in the chest was commonly complained of, usually either behind the sternum, basally, or just below the nipple. The respiration rate was greatly accelerated, even up to 60 per minute The pulse, however, was usually powerful The cough was short and hacking initially, but later was softer, when sputum was being expectorated Cyanosis was observed in many of these pneumonic cases.

Cyanosis A characteristic feature of the disease was a heliotrope cyanosis, involving the face and chest and sometimes other parts of the body (for illustrations see Abrahams, Hallows, and French, 1919, French, 1920) French estimated that approximately half the cases of pneumonia had flushed red faces while the remainder were cyanosed He estimated the mortality rate of cyanotic cases at 95 per cent, the patient might die in 24 hours or linger for as long as a week Another characteristic appearance was a vermilion color of the pharynx and soft palate (see Bloomfield and Harrop, 1919)

Other complications No attempt will be made to discuss complications other than pneumonia. The following list of possible complications is that given by French. epistaxis, hemoptysis, and hematemesis, subsultus and delirium, rupture of the rectus muscle, superficial thoracic emphysema, sinusitis, parotitis, otitis media, and meningitis, jaundice and nephritis, herpes.

Sequelae Even in comparatively mild cases return to health was slow. There was intense physical and mental weakness, the patients being usually unfit for any exertion, and depression was common.

The blood picture Numbers of authors studied the blood picture in influenza (e.g, Bloomfield and Harrop, 1919, Chickering and Park, 1919, Camp Lewis Pneumonia Unit, 1919, Bunting, 1921) It is probable that in the early stages there was a neutrophilia which was shortly followed by the characteristic leukopenia, there

might be a degree of absolute lymphocytosis. Leukocytosis might be observed in cases complicated by pneumonic conditions.

BACTERIOLOGY OF PANDEMIC INFLUENZA

Needless to say, influenza attracted the widest interest, and countless workers reported the results of their bacteriological investigations (e.g., in *Great Britain*: Influenza Committee, 1918, Fildes, Baker, and Thompson, 1918, Hopkins, 1918–19, McIntosh, 1918, 1922, Whittingham and Sims, 1918, Logan, 1919, 1921, Fildes and McIntosh, 1920, Scott, 1922, Donaldson, 1922, in *France*: Influenza Committee, 1918, Tytler, Janes, and Dobbin, 1919, Gibson and Bowman, 1919, in the *United States*: Blanton and Irons, 1918, Camp Lewis Pneumonia Unit, 1919, Park, 1919, Pritchett and Stillman, 1919, Stone and Swift, 1919, Williams, 1919; Opie *et al.*, 1919 *b*, in *Germany:* Bernhardt, 1918, Dietrich, 1918, Simmonds, 1918, in *India:* Greig, 1920–1). Those who desire fuller information should consult Thomson and Thomson (1933, 1934) or Jordan (1927).

Specimens were usually taken from throat swabs, gargling, or sputa *B. influenzae* * was frequently found in such specimens, either in pure culture or more frequently along with the usual throat flora. In fact, certain observers found the organism in over 80 per cent of cases A fuller discussion of the rôle of *B influenzae* is found below

A variety of organisms was isolated by postmortem lung culture. The severest lesions were produced by *B. influenzae*, *Pneumococcus*, hemolytic streptococcus, and *Staphylococcus aureus*. In certain cases nonhemolytic streptococci were isolated (e g, by Blanton and Irons, 1918, Gibson and Bowman, 1919). *Neisseria* organisms were also isolated, some at least being true meningococci (Fletcher, 1919)

With regard to serological observations, it was reported that the sera of influenza convalescents fixed complement with influenza bacilli as antigen, and that agglutination also occurred (e g, Sobernheim and Novakovic, 1918, Gibson and Bowman, 1919, Gay and Harris, 1919, Rapoport, 1919, Scheer, 1919, Cooke, 1920, McIntosh, 1922, Sharp and Jordan, 1924) The agglutination was probably not specific, as serum of measles convalescents was also found to agglutinate *B. influenzae* (Sharp and Jordan)

MORTALITY

Although the total number of deaths throughout the world was enormous, the average mortality rate was not much over 3 per cent Death was invariably produced by some respiratory complication French (1920) found that about 20 per cent of cases developed pneumonia in the 2 later waves, and of these nearly half died In the United States of America it was estimated that 550,000 deaths occurred, and in Great Britain 220,000 In the whole world the total death rate probably amounted to over 20 million (Jordan, 1927). The majority of deaths occurred in persons between 15 and 45, especially in the later waves This feature was unusual as previously influenza, even in pandemic form, had tended to show maximum mortality figures for those over 60 years of age The tendency to cause a fatal result in young adults was one of the main characteristics of pandemic influenza in 1918–19 The pandemic increased the total death rates, deaths from respiratory diseases, and deaths from diseases of various other systems, such as the heart

PATHOLOGY

The Respiratory System

Virtually every fatal case of influenza in 1918–19 presented evidences of pulmonary involvement, the other organs of the body being only slightly affected

* In this chapter we retain the old name, *B influenzae*, rather than *Haemophilus influenzae* which has come into general use only since the days of pandemic influenza

The lesions varied from case to case and locality to locality. Many of these were quite novel and were studied by numerous authors, of whom only comparatively few can be mentioned by name (Fildes, Baker, and Thompson, 1918; Lubarsch, 1918, Oberndorfer, 1918; Simmonds, 1918, Hopkins, 1918–19, LeCount, 1919 *a, b, c*, Champtaloup and Drennan, 1919; Chickering and Park, 1919; Connor, 1919, Goodpasture, 1919 *a, b*; Goodpasture and Burnett, 1919, MacCallum, 1919, Opie *et al*, 1919 *b*; Stone and Swift, 1919; Sundell, 1919; Tytler, Janes, and Dobbin, 1919, Wolbach, 1919, French, 1920, McNamara, 1920, Symmers, Dinnerstein, and Frost, 1920). In addition, Opie (1928) has reviewed the writings of British and American authors, while Luksch (1928) has reviewed the German work. French (1920) appends to his article a full bibliography.

We shall describe the changes that might be encountered, first on an anatomical, and later on a bacteriological, basis

1. *Pleural inflammation.* Fibrinous exudates were commonly found overlying areas of consolidation, in other cases the pleural cavities contained varying quantities of blood-stained serous fluid. Empyemata were seen in certain cases, although sometimes it was difficult to find lesions in the lung; the causal organism in such cases was usually the hemolytic streptococcus.

LeCount (1919 *a*) drew attention to a lesion which he regarded as almost pathognomonic the subpleural area was distended with fluid and in parts the pleura was raised off the lung in characteristic plaques, through which some of the usual carbon mottling could be seen.

2. *Tracheitis and bronchitis* The trachea, bronchi, and bronchioles were usually acutely inflamed, and frequently contained purulent exudate. Bronchiectatic dilatation was observed in some cases of longer duration.

3. *Capillary necrosis* LeCount (1919 *b*) described disseminated necrosis of the interalveolar capillaries, best seen in small pneumonic areas. There was little cellular exudate associated with this necrosis of the interalveolar network. The necrosis was probably a purely toxic reaction and appears to have been responsible for the characteristic hemorrhages.

4 *Hemorrhages* The appearance of red hemorrhagic infarcts was one of the most characteristic features of the pathology, these were found subpleurally and in the lung parenchyma Microscopically, hemorrhage was frequently seen in the alveoli in areas where no gross hemorrhage might be visible naked-eye

5 *Interstitial emphysema.* This might follow necrosis of the alveolar and interalveolar tissue, when air tracked along the interstitial tissue to the hilum, and thence to the mediastinum

6 *Edema* The lungs were often bulky and edematous, and on section great quantities of hemorrhagic fluid escaped At the autopsy the bronchi and trachea were filled with fluid, which even ran out of the mouth and nostrils

7 *Abscesses* Abscesses were sometimes found in the lungs, especially in staphylococcal pneumonia, and might occur in the center of a patch of consolidation, subpleurally, or peribronchially

8 *Hyaline membrane* Certain authors recorded the presence of dilatation of the *ductuli alveolares* associated with a hyaline membrane covering the alveolar walls (Goodpasture, 1919 *a, b*, LeCount, 1919 *b*, MacCallum, 1919, Wolbach, 1919) The membrane was of irregular thickness and might completely fill an alveolus, being most conspicuous in acute pneumonia of short standing It did not give fibrin reactions, but was thought to be derived therefrom, along with necrotic cells, it was probably produced by the action of the virus *per se* and not by any particular type of secondary bacterial invader In 2 cases hyaline membrane was found in lungs that proved sterile on routine cultural examination, thus suggesting that the virus alone was responsible (Goodpasture)

Regarding the source of the alveolar fibrinous exudate, Wolbach has suggested that it is formed by the entrance of secretion from the bronchioles and alveolar

ducts at a time when air can enter to distend the alveoli Although formerly regarded as a specific feature of influenza, this is probably not now acceptable Thus Brannan and Goodpasture (1924) found a similar membrane in 2 cases definitely not influenzal, while Farber and Sweet (1931) found a similar membrane in the bronchioles and alveoli of newborn children, as a reaction to the presence of amniotic fluid The membrane was fatty and stained with scharlach R

9. *Fulminating influenza* In these cases death usually supervened a few hours after onset At *postmortem* the lungs were voluminous and on section poured out edematous fluid, subpleural and parenchymal hemorrhages were present

10. *Pneumonic consolidation* The majority of cases presented evidences of some consolidation, lobar or bronchopneumonic in distribution. Lobar pneumonia was more commonly reported in some areas than others, thus Opie *et al.* (1919 *b*), at an American army camp, found it in 50 per cent. of autopsies The more usual finding elsewhere, however, was bronchopneumonia, lobar pneumonia was only rarely found (e g, by French, 1920).

The characteristic bronchopneumonic nodules were reddish-gray in color and either discrete or confluent. The cut surface of the lung was usually hemorrhagic, and the bronchi contained purulent exudate. The pneumococcus, hemolytic streptococcus, and Pfeiffer's bacillus were frequently isolated from these cases (*vide infra*). In the earlier cases in the autumn of 1918 the bronchopneumonia was said to be more of a toxic injury than an inflammation, with hemorrhage and exudation of fibrin into the alveoli (see, e g, Goodpasture, 1919 *a*). In the early months of 1919, however, the same observer reported a more inflammatory type of reaction There were grayish-purple areas of lobular consolidation and much pus, while, microscopically, streptococci and pus cells were seen in the alveoli.

11. *Repair.* McNamara (1920) in particular has drawn attention to the reparative process that might be seen. Thus bronchiolar and alveolar exudates underwent organization with resultant fibrosis and bronchiectasis He also described an unusual, almost neoplastic-like, proliferation of the epithelium lining the bronchioles

An attempt was made to classify certain types of pneumonia according to the causal organism.

[illegible]

present, usually in the dependent parts of the organ These abscesses were clearly visible subpleurally and might be associated with pleural exudation. The lung usually showed, in addition, numerous hemorrhagic areas (see also Tytler, Janes, and Dobbin, 1919).

(*b*) *Pneumococcal pneumonia* A number of authors isolated pneumococci from the lung (e g, Blanton and Irons, 1918, Pritchett and Stillman, 1919, Logan, 1919, 1921, Opie *et al*, 1919 *b*) This condition was especially studied from the pathological point of view by MacCallum (1919). [illegible]
mal pleurae and bronchi, but, on section, [illegible]
areas could be seen quite clearly demarcatec [illegible]

[illegible]

alveoli contained fibrin, leukocytes, and organisms.

(*c*) *Streptococcal pneumonia* Hemolytic streptococci were frequently isolated in certain localities (e g, by Blanton and Irons, 1918, Fildes, Baker, and Thompson, 1918, Goodpasture, 1919 *a*, Opie *et al*, 1919 *b*) Goodspasture reported that hemolytic streptococci were more commonly encountered in the cases which he examined in December 1918 and January 1919 than in those occurring in the fall of 1918 Pneumonia due to the hemolytic streptococcus had a characteristic appear-

ance (see MacCallum, 1919)· there was a scanty pleural exudate, edema of the interlobular septa, while deep red consolidated areas, not sharply demarcated, were also present. Microscopically, the alveoli contained leukocytes, blood, fibrin, and streptococci, the alveolar vessels contained fibrinous thrombi. The bronchi also contained exudate and streptococci, and their epithelium was widely necrotic.

(*d*) B influenzae *pneumonia*. Pfeiffer's bacillus was frequently found in the lungs of fatal cases of influenza (e.g., by Dietrich, 1918; Simmonds, 1918, McIntosh, 1918, Opie *et al.*, 1919 *b*; Spooner, Scott, and Heath, 1919, Tytler, Janes, and Dobbin, 1919, Wolbach, 1919; Greig, 1920–1). According to MacCallum (1919), the pneumonia associated with Pfeiffer's bacillus had characteristic features, justifying the designation of "interstitial pneumonia." Pleural exudate was not usually prominent, but the surface might be covered with fibrin On section, the lung surface showed numerous yellowish peribronchial nodules, almost resembling tubercles, and purulent bronchitis was usually present. Microscopical examination of the nodules showed that the alveoli contained a leukocytic exudate with little hemorrhage. There was proliferation and infiltration of the walls of the bronchioles and alveoli

Summary. It is thus evident that numerous types of lesion might be found in influenza. In fact, the heterogeneity of the pathological pictures was one of the characteristic features of the disease. Generally speaking, in the earlier cases the lesions were mainly of a toxic nature, the lungs showing numerous hemorrhages. In the 1919 (third) wave the rôle of secondary organisms was firmly established and the lesions then produced were of a different nature. The essential changes were a necrotizing type of inflammation of the bronchi and bronchioles.

Other Organs

Purulent sinusitis was very commonly observed, and otitis media might also be present. The meninges were often edematous and the brain tissue congested Hemorrhages might be observed in the rectus abdominis, and Champtaloup and Drennan (1919) recorded a waxy degeneration of voluntary muscles. Mills (1919) reported cellular desquamation in the testis, and infiltration with giant cells

There was usually evidence of cloudy swelling or fatty degeneration in the liver, while in the kidney French (1920) found frequently a state of general vascular congestion He also drew attention to enlargement and congestion of lymph glands, especially below the bifurcation of the trachea

EPIDEMIOLOGY OF PANDEMIC INFLUENZA

The epidemiology of influenza proves an interesting study, and it is regretted that it can only be dealt with here quite shortly, and that with especial reference to the state of affairs in Great Britain Bruce Low (1920) collected the epidemiological data relative to Europe, while James (1920) did so for Australasia and the East The monograph of Burnet and Clark (1942) gives a wealth of valuable information on epidemiology.

Characters of the Various Waves of Influenza

The pandemic influenza of spring, 1918, is often known as "Spanish influenza," but it is uncertain that the disease actually broke out first in Spain. In fact, it is more probable that the earlier cases occurred in France From France, the main battle front of World War I, the disease seemed to spread all over the world In many places 3 distinct waves were experienced

First wave. In April 1918 the disease broke out in the French and British armies fighting in France In the British armies the first cases occurred at Rouen and Wimereux (Influenza Committee, 1918) The peak was experienced about June 25 and the epidemic was virtually over by mid-August In the United States the first

cases were probably seen in Chicago during the first week in April 1918, but it was not until later, when postmortem examinations were carried out by LeCount (1919 *c*), that it was realized that the condition was influenza

Great Britain was attacked rather later than France, about June The disease involved Germany and Italy slightly later Definite influenzal outbreaks were also experienced in India and New Zealand in July, although Australia escaped In August, South Africa was involved

The first wave was comparatively mild, and the term "3-day influenza" was sometimes applied, pneumonic complications were rare

Second wave This wave was very much more severe and had a considerably higher death rate The outbreak was at its height in September and October in France, Great Britain, and America, almost all parts of the world were involved in this wave

Third wave This wave occurred in February and March 1919, particularly in the United States and in Great Britain, and was the severest of the three in certain localities, in other areas, however, it was less severe than the second wave

Attack Rate

Estimates of the number of persons attacked varied considerably, but probably up to half the population of the world would be a fair estimate. The majority of cases occurred in persons under 20 years of age In the United States it has been reported that there was a higher attack rate in the poorer than the richer classes (Sydenstricker, 1931)

Spread

Weather did not play any primary part in the spread of the epidemic, at any rate in Great Britain (Ministry of Health, 1920) The disease must have been spread by droplet infection As the virus had not been isolated in those days it was not possible to say accurately for how long an influenzal patient was infective. Probably, however, the virus was only present in the nose and throat for a few days during the acute stages, and for a few hours in the incubation period

There were numerous instances where influenza broke out in communities fol- [illegible] sponsible for the spread of the disease by droplets, in certain cases, especially in institutions, infection may have been contracted from fomites, such as improperly cleansed eating utensils

Although epidemiological observations rendered it certain that infection was spread by droplets of infective secretion, experiments to test this hypothesis failed, because volunteers inoculated with the throat secretions of cases of influenza did not contract the disease (see, e g, McCoy and Richey, 1921, Rosenau *et al*, 1921).

Periodicity of the Waves of Pandemic Influenza

It has been shown how the 1918–19 pandemic was composed of 3 distinct waves Influenza was also prevalent during the few succeeding years In the 1890 pandemic also there were similar waves and recurrences Brownlee (1920, 1923) has postulated a 33-week cycle for these recurrent outbreaks, basing his hypothesis on a number of British and American statistics It may be said that the existence of this cycle has not been definitely accepted by the majority of epidemiologists.

Etiology of Influenza Pandemics

One is faced with difficulty in attempting to account for the occurrence of influenza in pandemic form on certain occasions in the world's history. It is evident

that either the host or the etiological agent may be responsible With regard to the host, in certain diseases (e g., measles, see Ch XX) *it is possible partly to explain the* occurrence of epidemics on a basis of rise and fall in the number of susceptibles Such an explanation might be offered in influenza (see Hamer, 1933–4). However, it is obvious that there is a long period of years in between pandemics, e g, in 1918 nearly 30 years had elapsed since the last pandemic. Now, as it is known that the immunity in influenza is only transient, probably lasting only a few months (*vide infra*), it is difficult to see how this theory can serve, as pandemics should occur much more often than they actually do.

Jordan (1927) has fully discussed the problem of pandemic influenza He suggests that a "pandemic strain" of virus arises with unusual characters After the pandemic it probably disappears (see, also, Picken, 1941). The characteristics of an influenza pandemic are thus assumed to be dependent on factors inherent in the causal agent, rather than the potential host, and of recent years it has been suggested that the 1918 pandemic human strain of virus did have special characteristics On the basis of serological tests it has been postulated that the 1918 human strain does not now affect man, but causes in pigs the condition of swine fever. Supported by Laidlaw and by Shope, this explanation of the observed serological data is not accepted by others, who feel that there may be another interpretation This subject is more fully discussed below (see p. 667).

Another explanation is that there was a high incidence of secondary bacterial invaders, and Shope (1944) suggested that this occurred in the second wave, the first being a pure virus infection.

Burnet and Clark (1942), who discuss in some detail the above alternatives, suggest for their own part that the 1918–19 pandemic virus, while similar antigenically to present-day virus A, possessed the unique biological property of attacking the alveoli as distinct from the bronchi, and perhaps of affecting vascular endothelium also. They consider that the abnormal conditions in France during the latter years of World War I, especially the great opportunities for transfer of infection by droplets, may have favored the emergence of a strain or strains with these highly "pneumotropic" properties There seems little doubt that secondary invaders played a definite rôle, and determined the severity of pneumonic complications Burnet and Clark suggest that by the end of 1919 the virulence of most strains was considerably reduced, probably owing to passage through partly immune persons

It is not our intention to theorize on this point any further, and we must close with an admission of present uncertainty. It does not seem that the problem can be solved unless another pandemic appears. If this unfortunate event should occur, it ought to be comparatively simple to test the new strains of virus and compare them antigenically and by animal test with known epidemic strains

IMMUNITY

There was some doubt as to whether one attack conferred resistance against a subsequent attack, and undoubtedly some reports seemed to indicate that there was a transient immunity acquired in convalescence Thus, Scoccia (1918) in Italy reported that sufferers from the May-June wave did not again contract the infection in September In India, Malone and McKendrick (1919–20) also reported an immunity lasting approximately 9 months Similar resistance to second attacks was reported by other workers (e g, Hamilton and Leonard, 1919, Speares, 1919, Waters, 1920)

A very thorough study of this question was undertaken by the United States Public Health Service in Baltimore (see Jordan, 1927) This work showed that any such immunity had quite waned after a year Thus they found that approximately 8 per cent. of persons who had influenza in 1918 were attacked in January and February 1920, and the same number of persons who had not suffered from the

1918 attack developed the disease in 1920. Similar observations were recorded by Jordan and Sharp (1920) and by Vaughan (1921)

With regard to passive immunity, certain workers reported beneficial effects following the use of human convalescent serum (see, e g, Grigaut and Moutier, 1918, McGuire and Redden, 1918, 1919, Gould, 1919, Francis, Hall, and Gaines, 1920, Sanborn, 1920).

ATTEMPTED ISOLATION OF THE ETIOLOGICAL AGENT OF PANDEMIC INFLUENZA

Although it is now almost certain that the cause of pandemic influenza was a filtrable virus, no such conclusion was reached in those days. Various theories were discussed first, that Pfeiffer's bacillus was the cause of pandemic influenza, second, that the disease was caused by a virus, pathogenic bacteria being associated as secondary invaders in certain, usually fatal, cases, and thirdly, Olitsky and Gates (1922, 1923) advanced the claims of *Bact pneumosintes*.

1. The Rôle of *B. influenzae*

Pfeiffer (1893) isolated *B influenzae* from cases of influenza and claimed it as the etiological agent. Almost from the start the primary relationship of this organism to the disease was doubted, for the following reasons

(*a*) *Distribution in influenza cases* Although during the pandemic (1918) the organism was frequently isolated from the upper respiratory tract and from the lungs (*vide supra*), a number of careful observers either failed to isolate it from genuine cases, or else found it to occur only in small numbers in the cultures (e g, Bernhardt, 1918, Blanton and Irons, 1918, Influenza Committee, 1918, Mandelbaum, 1918, Camp Lewis Pneumonia Unit, 1919).

(*b*) *Distribution in other conditions.* One of the most serious and old-standing objections to accepting Pfeiffer's bacillus as the primary agent of influenza has been that it is often found in other conditions (see Leiner, 1901, Rosenthal, 1905, Wollstein, 1906) During the pandemic numerous authors found it in the throats of normal persons, in some cases even up to 40 per cent. (see, e g, Fildes, Baker, and Thompson, 1918, Kinsella, 1919, Lord, Scott, and Nye, 1919, Opie *et al*, 1919 *a*, *b*, Pritchett and Stillman, 1919, Scott, 1922)

(*c*) *Serological structure of* B influenzae There was great unanimity regarding the antigenic structure of this organism, which was extensively investigated (Fleming and Clemenger, 1919, Park, Williams, and Cooper, 1919, Park and Williams, 1919, Rapoport, 1919, Valentine and Cooper, 1919, Bell, 1920, Small and Dickson, 1920, Coca and Kelley, 1921, Jordan and Sharp, 1922, Scott, 1922). These workers showed that there were numerous different types, and the pandemic, or even small localized sections of it, was definitely not caused by strains serologically identical. In fact, a number of different strains might be isolated from one person These findings could not be [illegible]
of influenza It is now [illegible]
there is a number of [illegible]

(*d*) *Pathogenicity* [illegible]
[illegible]

fluenzae for man, certain volunteers have been inoculated in the throat with cultures Some have reported that influenza did not follow such inoculations (Lister and Taylor, 1919, Rosenau, 1919, Yamanouchi *et al*, 1919, Ishiwara, 1923). Others have reported slight rises of temperature, with pains and perhaps respiratory symptoms, and even some prostration (Davis, 1919, Cecil and Steffen, 1921, Park and

Cooper, 1921). These attacks, however, were not nearly so severe as typical influenza

Recently Smorodintseff *et al.* (1936 *a*) have carried out a carefully controlled series of experiments in Russia. They inoculated human volunteers with cultures of Pfeiffer's bacillus, and after 4 to 6 hours noted the development of coryza with slight rise of temperature. These symptoms soon subsided and were definitely not those of a genuine influenza.

It is probable that *B. influenzae* can cause a purulent bronchitis (Mulder, 1940 *b*)

Conclusions. We can only conclude that Pfeiffer's bacillus was not the causal agent of pandemic influenza. In like manner, it is definitely not the cause of epidemic influenza. This is not to deny any rôle to Pfeiffer's bacillus, for during the pandemic it was undoubtedly of importance as a secondarily invading organism

2. The Virus Theory

Many bacteriologists began to feel that *B. influenzae* was not the causal agent of pandemic influenza, and in the absence of any other organism occurring regularly, suspicion fell on the possibility of a filtrable virus being present. Many experiments were carried out which did little or nothing to support this theory, because filtrates of nasopharyngeal secretion of cases did not produce definite influenza in inoculated volunteers (see, e.g., Keegan, 1918; Lister and Taylor, 1919; Rosenau, 1919, *et al.*, 1921, McCoy and Richey, 1921).

Moreover, it must be admitted that even today, when the virus theory of influenza is generally accepted, filtrates of nasopharyngeal secretion may not transmit influenza. Thus Dochez, Mills, and Kneeland (1936) only produced a common cold in certain experiments

However, certain workers obtained more positive results Nicolle and Lebailly (1919) claimed to have transmitted influenza to 2 persons by a subcutaneous inoculation of filtered sputum The same workers also claimed positive inoculations of monkeys by the nasal route. In Japan, Yamanouchi *et al* (1919) claimed to have transmitted the infection to a number of volunteers by injection of filtered and unfiltered sputa intranasally and subcutaneously, blood of acute cases was also said to prove infective. Selter (1918) and Leschke (1919) also reported somewhat similar results

Gibson, Bowman, and Connor (1918, 1919), and guinea-pigs, reported the production of ıfluenza, after inoculation with filtered and her, they reported that their "virus" could be cultured in Noguchi's medium, when a growth of a minute coccus was obtained In view of our present knowledge of the properties of the influenza virus, *it is* most unlikely that these workers really isolated the causal agent.

In conclusion, it is evident that the virus theory, though attractive, was not supported by much experimental work, and probably derived its main support from the fact that no cultivable organism seemed to be responsible.

3. The Rôle of *Bacterium Pneumosintes*

This coccobacillus is a small filter-passing organism which was isolated from the nasopharyngeal washings of cases of catarrh of the upper respiratory tract by Olitsky and Gates (e g, 1922, 1923) Although it is probably a specific organism it is unlikely that it is causally related to influenza (for further information see McCartney, 1929)

CHAPTER LV

EPIDEMIC INFLUENZA

Introduction

In 1933 many believed human influenza to be a virus disease, but this theory rested on no certain foundations. Progress was hindered by the lack of an animal to which the disease could be readily and economically transmitted Accordingly, the widest interest was taken in a paper published from the National Institute of Medical Research, London, by Smith, Andrewes, and Laidlaw (1933).[1] They reported the susceptibility of the ferret to a filtrable virus present in the nasopharyngeal secretions of typical cases of epidemic influenza. As the filtrable virus was recovered from a number of cases there appeared little doubt that it was actually the cause of epidemic influenza, especially as it was not isolated from sporadic or vague "influenzal" cases Later it was reported that mice could be infected with this virus, thus considerably facilitating research (Andrewes, Laidlaw, and Smith, 1934).

Francis (1934) in the United States was able to confirm the presence of such a virus in the sputum of cases in Puerto Rico Later (1934–5) he found the virus in New York and Philadelphia (see also 1935) Since this time many workers have isolated strains of virus from cases of epidemic influenza, and it is now universally accepted as the etiological agent.

Following the suggestion of Horsfall *et al* (1940), influenza virus strains are separated into 2 main types, the original or Type A, which includes the well-known WS and PR8 strains, and the more recently discovered Type B including the Lee and TM strains These types resemble each other closely in biological properties but can be differentiated antigenically.

Very remarkable advances have been made in influenza research of recent years For example, it has been found that the virus grows readily in the allantoic and amniotic sacs, in the former in such abundance that it can be obtained in large enough quantity for vaccine production It has also been shown that virus causes agglutination of chick and other red cells, and that sera containing influenzal antibody inhibit this agglutination

A condition closely resembling human influenza has been observed in swine since 1918 This disease, known as swine influenza, occurs commonly in the Middle West of the United States Although the condition does not, so far as is known, affect man, it presents so many analogies to the human disease, and the causal viruses are so closely related, that it will be described below in some detail. It has, moreover, been suggested that the present virus of swine influenza is the modern survivor of the 1918 pandemic human strain

A number of general reviews on the subject of influenza has appeared of recent years (Laidlaw, 1934, 1935, Shope, 1936 *c*, *d*, 1944; Andrewes, 1937, 1939, 1942 *b*, Béclère, 1937, Francis, 1937, 1938, 1941 *a*, 1947 *b*, Hallauer, 1937, Burnet, 1943 *c*, Parodi and Vilches, 1944, Stuart-Harris, 1940, 1945 *a*, *b*, 1947), Burnet and Clark (1942) have published a particularly valuable monograph.

Swine Influenza[2]

The disease was first noticed in the Middle West of the United States of America in 1918, affecting many stocks of pigs in the Iowa district, with a high mortality. At the same time, the pandemic of human influenza was raging, and Koen suggested that the two diseases might be the same (see Dorset, McBryde, and Niles, 1922–3, also McBryde, 1927)

[1] References are appended at the conclusion of Ch LXIII, p 671 et seq

[2] Much additional information about the swine influenza virus will be found in the following chapters

Koen suggested that the pigs were infected initially from human beings Of recent years this suggestion has been amplified, and it is suggested that the original 1918 human strain no longer exists in man, but only in the pig, as one of the causal agents of swine influenza Shope has shown that the malady is caused by a synergism of a filtrable virus and a hemophilic bacterium

Swine influenza occurs also in Europe, Great Britain, and N Ireland, and apparently organisms other than *H. suis* may occur along with the virus (Blakemore and Gledhill, 1941; Glover, 1941 *a;* Glover and Andrewes, 1943).

Features. The features in pigs are virtually identical with those produced by the combined injection of the 2 causal agents under experimental conditions. The disease occurs mainly in the autumn and early winter. The onset is sudden and many animals die, the course is manifested by fever, cough, and prostration (see Shope, 1931 *a*).

Pathology Swine influenza is characterized pathologically by an exudative bronchitis and bronchiectasis (Shope, 1931 *a*, 1936 *c*). There is massive pulmonary atelectasis with pneumonic consolidation Microscopically, a polymorph exudate fills the bronchi and bronchioles, the lining membrane of the bronchial tree is severely affected and the cilia are lacking or damaged in many areas The cervical and bronchial lymph glands are edematous and enlarged
